the line center. Combined with the reduced blue-side flux, the overall profile has a distinctly asymmetric form, with apparent net blueward absorption and redward emission. Moreover, the wavelength of the blue edge of the absorption provides a quite unambiguous measure of the asymptotic wind speed, v_∞.

The radiative force from electron scattering

A radiative force results from the material interception of radiative momentum. A particularly simple case is scattering by free electrons, which is a 'gray', or frequency-independent, process. Since gray scattering cannot alter the star's total luminosity L, the radiative energy flux at any radius r is simply given by $L/4\pi r^2$. This corresponds to a radiative momentum flux of $L/4\pi r^2 c$, where c is the speed of light. The material interception of this flux is characterized by an interaction cross section per unit mass, κ, which is formally named the 'mass absorption coefficient' but more succinctly is also commonly called the 'opacity'. For electron scattering in an ionized medium, the opacity is simply a constant given by $\kappa_e = \sigma_e/\mu_e$, where σ_e (=0.66 $\times$ 10^{-24} cm^2) is the classical Thompson cross section, and the mean atomic mass per free electron is $\mu_e = 2m_H/(1+X)$, with m_H and X the mass and mass fraction of hydrogen. This works out to a value $\kappa_e = 0.2(1+X) = 0.34$ cm^2 g^{-1}, where the latter result applies for the standard (solar) hydrogen mass fraction $X = 0.72$. The product of this opacity and the radiative momentum flux yields the radiative acceleration (force per unit mass) from free-electron scattering,

$$g_e(r) = \frac{\kappa_e L}{4\pi r^2 c}.$$

It is of interest to compare this with the star's gravitational acceleration, given by GM/r^2, where G is the gravitation constant and the M is the stellar mass. Since both accelerations have the same $1/r^2$ dependence on radius, their ratio is spatially constant, fixed by the ratio of luminosity to mass,

$$\Gamma_e = \frac{\kappa_e L}{4\pi G M c}.$$

This ratio, sometimes called the Eddington parameter, thus has a characteristic value for each star. For the Sun it is very small, of order 2 $\times$ 10^{-5}, but for hot, massive stars it is often within a factor of 2 below unity. As noted by Eddington, electron scattering thus represents a basal radiative acceleration that effectively counteracts the stellar gravity. The limit $\Gamma_e \to 1$ is known as the Eddington limit, for which the star would become gravitationally unbound.

It is certainly significant that hot stars with strong stellar winds have Γ_e only a factor of 2 or so below this limit, since it suggests that only a modest additional opacity could succeed in fully overcoming gravity to drive an outflow. However, it is important to realize that a stellar wind represents the outer envelope outflow from a nearly static, gravitationally bound base, and as such is not consistent with an entire star exceeding the Eddington limit. Rather the key requirement for a wind is that the driving force increase naturally from being smaller to larger than gravity at some radius near the stellar surface. We shall now see that the force from line scattering is ideally suited for just such a spatial modulation.

The Doppler-shifted resonance of line scattering

When an electron is bound into one of the discrete energy levels of an atom, its scattering of radiation is primarily with photons of just the right energy to induce shuffling with another discrete level. The process is called line scattering, because it often results in the appearance of narrowly defined lines in a star's energy spectrum. At first glance, it may seem unlikely that such line scattering could be effective in driving mass loss, simply because the opacity only interacts with a small fraction of the available stellar flux. However, there are two key factors that work to make line scattering in fact the key driving mechanism for hot-star winds.

The first is the resonant nature of line scattering. The binding of an electron into discrete energy levels of an atom represents a kind of resonance cavity that can greatly amplify the interaction cross section with photons of just the right energy to induce transition among the levels. The effect is somewhat analogous to blowing into a whistle versus just into open air. Like the sound of a whistle, the response occurs at a well-tuned frequency and has a greatly enhanced strength. Relative to free-electron scattering, the overall amplification factor for a broad-band, untuned radiation source is set by the quality of the resonance, $Q \approx \nu_0/A$, where ν_0 is the line frequency and A is the decay rate of the excited state. For quantum mechanically allowed atomic transitions, this can be very large, of order 10^7. Thus, even though only a very small fraction ($\sim 10^{-4}$) of electrons in a hot-star atmosphere are bound into atoms, illumination of

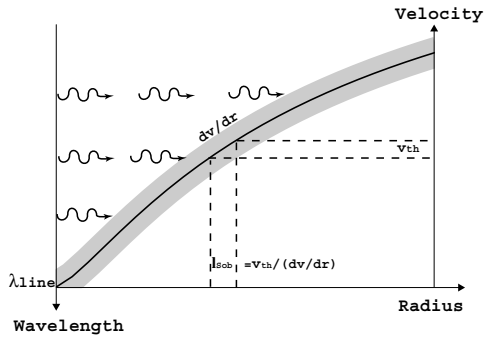

Figure 2. Doppler-shifted line resonance absorption in an accelerating flow. Photons with a wavelength just shortward of a line propagate freely from the stellar surface until redshifted, within a reference frame moving with the wind outflow velocity, into a narrow line resonance, whose width is set by the thermal broadening of the line, as represented here by the shading.

these atoms by an unattenuated (i.e. optically thin), broad-band radiation source would yield a collective line force that exceeds that from free electrons by about a factor $\bar{Q} \approx 10^7 \times 10^{-4} = 1000$. For stars within a factor of 2 of the free-electron Eddington limit, this implies that line scattering is capable, in principle, of driving material outward with an acceleration on the order of a thousand times the inward acceleration of gravity.

In practice, of course, this does not normally occur, since any sufficiently large collection of atoms scattering in this way would quickly block the limited flux available within just the narrow frequency bands tuned to the lines. Indeed, in the static portion of the atmosphere, the flux is greatly reduced at the line frequencies. Such line 'saturation' keeps the overall line force quite small, in fact well below the gravitational force, which thus allows the inner parts of the atmosphere to remain gravitationally bound.

This, however, is where the second key factor, the Doppler effect, comes into play. In the outward-moving portions of the outer atmosphere, the Doppler effect redshifts the local line resonance, effectively desaturating the lines by allowing the atoms to resonate with relatively unattenuated stellar flux that was initially at slightly higher frequencies. By effectively sweeping a broader range of the stellar flux spectrum, this makes it possible for the line force to overcome gravity and accelerate the very outflow it itself requires. As quantified within the CAK wind theory described later, the amount of mass accelerated adjusts such that the self-absorption of the radiation reduces the overall line driving to being just somewhat (not a factor of 1000) above what is needed to overcome gravity.

The Sobolev approximation for line scattering in an accelerating flow

The late Russian astrophysicist V V Sobolev developed an extremely useful approach for treating line scattering in such a rapidly accelerating flow. As illustrated in figure 2, he noted how radiation emitted from the star at a wavelength somewhat blueward of a line propagates freely until it is redshifted by the accelerating flow into a local line resonance. For the usual case that the broadening of the line is set by the ion thermal speed $v_{\rm th}$, the geometric width of this resonance is about a Sobolev length, $l_{\rm Sob} \equiv v_{\rm th}/(\mathrm{d}v/\mathrm{d}r)$. In a supersonic flow, this Sobolev length is of order $v_{\rm th}/v \ll 1$ smaller than a typical flow variation scale, like the density–velocity scale length $H \equiv |\rho/(\mathrm{d}\rho/\mathrm{d}r)| \approx v/(\mathrm{d}v/\mathrm{d}r)$.

The nearly homogeneous conditions within such resonance layers imply that the key parameters of the line scattering can be described in terms of strictly *local* conditions at any radius. In particular, the total optical depth of radiation passing through the line resonance—which normally requires evaluation of a nonlocal spatial integral—can in this case be well approximated simply in terms of the local density and velocity gradient,

$$\tau = \frac{\kappa \rho v_{\rm th}}{\mathrm{d}v/\mathrm{d}r} \tag{1}$$

where κ is the line opacity. This allows a localized solution for how much the flow absorption reduces the illumination of the line resonance by the stellar flux and leads to a simple, general expression for the line acceleration,

$$g_{\rm line} \approx g_{\rm thin} \frac{1 - \mathrm{e}^{-\tau}}{\tau}. \tag{2}$$

In the optically thin limit $\tau \ll 1$, the line acceleration reduces to a form similar to the electron scattering case,

$$g_{\rm thin} \equiv \frac{\kappa v_{\rm th} \nu_0 L_\nu}{4\pi r^2 c^2} \approx \frac{\kappa}{\kappa_{\rm e}} \frac{v_{\rm th}}{c} g_{\rm e} \tag{3}$$

wherein the last approximate equality applies the usual assumption that the line frequency ν_0 is near the peak of the stellar luminosity spectrum L_ν, so that $\nu_0 L_\nu \approx L$. In the opposite limit of an optically thick line with $\tau \gg 1$, there results a quite different form,

$$g_{\rm thick} \approx \frac{g_{\rm thin}}{\tau} = \frac{L}{4\pi r^2 \rho c^2} \frac{\mathrm{d}v}{\mathrm{d}r} = \frac{L}{\dot{M} c^2} v \frac{\mathrm{d}v}{\mathrm{d}r} \tag{4}$$

where the last equality uses the definition of the wind mass loss rate, $\dot{M} \equiv 4\pi \rho v r^2$.

A key result here is that the optically thick line force is independent of the opacity and instead varies in proportion to the velocity gradient $\mathrm{d}v/\mathrm{d}r$. The basis of this result is illustrated by figure 2, which shows that the local rate at which stellar radiation is redshifted into a line resonance depends on the slope of the velocity. By Newton's famous equation of motion, a force is normally understood to *cause* an acceleration. However, here we see that an optically thick line force also *depends* on the wind's advective rate of acceleration, $v\,\mathrm{d}v/\mathrm{d}r$.

Derivation of direct absorption force for a single line

Let us derive this key property of line driving in more quantitative terms. Under the simplifying approximation that the stellar radiation flux is purely radial (as from a central point source), the force per unit mass associated with direct absorption by a single line at a radius r is given by

$$g_{\rm line}(r) = g_{\rm thin} \int_{-\infty}^{\infty} {\rm d}x\, \phi[x - v(r)/v_{\rm th}]\, {\rm e}^{-t(x,r)}. \qquad (5)$$

The integration is over a scaled frequency $x \equiv (\nu/\nu_0 - 1)\, c/v_{\rm th}$, defined from a line center frequency, ν_0, in units of the frequency broadening associated with the ion thermal motion, $v_{\rm th}$. The integrand is weighted by the line profile function $\phi(x)$, which for thermal broadening typically has the Gaussian form $\phi(x) \sim {\rm e}^{-x^2}$. The exponential reduction takes account of absorption, as set by the frequency-dependent optical depth to the stellar surface radius R_*,

$$t(x, r) \equiv \int_{R_*}^{r} {\rm d}r'\, \kappa\rho(r')\phi[x - v(r')/v_{\rm th}].$$

A crucial point in evaluating this integral is that, in a supersonic wind, the variation of the integrand is dominated by the velocity variation within the line profile. As noted above, this variation has a scale given by the Sobolev length $l_{\rm Sob} \equiv v_{\rm th}/({\rm d}v/{\rm d}r)$, which is smaller by a factor $v_{\rm th}/v$ than the competing density–velocity scale, $H \equiv |\rho/({\rm d}\rho/{\rm d}r)| \approx v/({\rm d}v/{\rm d}r)$. A key step in the Sobolev approximation is thus to recast this spatial integration as an integration over the comoving frame frequency $x' \equiv x - v(r')/v_{\rm th}$,

$$\begin{aligned} t(x, r) &= -\int_{x'(R_*)}^{x'(r)} \frac{{\rm d}x'\, v_{\rm th}}{{\rm d}v/{\rm d}r'} \kappa\rho(x')\, \phi(x') \\ &\approx \tau(r) \int_{x - v(r)/v_{\rm th}}^{\infty} {\rm d}x'\, \phi(x') \end{aligned} \qquad (6)$$

where the latter approximation uses the assumption that $v(r) \gg v_{\rm th}$ to formally extend the surface frequency $x'(R_*)$ to infinity relative to the local resonance $x'(r)$. The quantity $\tau(r)$, which is just the local Sobolev optical thickness defined in equation (1), arises as a collection of spatial variables that are assumed to be nearly constant over the Sobolev resonance zone and thus can be extracted outside the integral.

Finally, a remarkable, extra bonus from this approximation is that the resulting optical depth (6) now has precisely the form needed to allow analytical evaluation of the line force integral (5), yielding directly the general expression given in equation (2).

The mass loss rate from inertial force balance

We can actually estimate the wind mass loss rate from a simple consideration of how this line force overcomes the wind inertia (for now ignoring gravity). For a single optically thick line near the peak of the stellar flux spectrum, the resulting steadystate flow acceleration is given by

$$v\frac{{\rm d}v}{{\rm d}r} = g_{\rm line} \approx \frac{L}{\dot{M}c^2} v \frac{{\rm d}v}{{\rm d}r}.$$

Since the acceleration cancels from both sides, this simply implies $\dot{M} \approx L/c^2$, or that the total mass loss of the wind is roughly equal to just the mass loss associated with the stellar luminosity. In practice, hot-star winds are driven by not just one but many optically thick lines. As long as these are independent of each other, the total resulting mass loss simply accumulates in proportion to the total number of thick lines,

$$\dot{M} \approx N_{\rm thick} \frac{L}{c^2}. \qquad (7)$$

For a wind with terminal speed v_∞, each line sweeps through about a fraction v_∞/c of the spectrum. This means that there can at most be about $N_{\rm thick} \approx c/v_\infty$ nonoverlapping thick lines spread throughout the spectrum. This implies a single-scattering limit for the mass loss,

$$\dot{M} v_\infty < \frac{L}{c}.$$

The winds from stars of spectral types O and B are generally within this limit, but winds from Wolf–Rayet (WR) stars can exceed it by a factor of 10 or more. As further discussed below, the driving of such WR winds thus requires a more intricate, multiline scattering process.

The CAK theory for line-driven winds

In practice, the number of thick lines depends itself on the mass loss rate and so is not known *a priori*. Self-consistent solution of the wind properties is possible, however, through the formalism developed by Castor, Abbott and Klein (CAK). A key simplification is to approximate the flux-weighted number distribution of lines as a power law in the line opacity κ,

$$\frac{{\rm d}N}{{\rm d}\kappa} = \frac{1}{\kappa_0} \left(\frac{\kappa}{\kappa_0}\right)^{\alpha-2}$$

where the CAK power-law index satisfies $0 < \alpha < 1$, and κ_0 is a normalization constant defined such that $\kappa_0\, {\rm d}N/{\rm d}\kappa \equiv 1$. (The latter is related to the commonly defined CAK constant k by $k = \Gamma(\alpha)(v_{\rm th}/c)(\kappa_0/\kappa_{\rm e})^{1-\alpha}/(1-\alpha)$, where Γ denotes the complete gamma function.) The cumulative force from this line ensemble can be obtained by an integration of the single-line result (2) over this opacity distribution. This yields a kind of 'geometric mean' between the optically thin and thick forms (equations (3) and (4)) for a single line,

$$g_{\rm cak} = \frac{g_{\rm thin,o}}{\tau_{\rm o}^{\alpha}}. \qquad (8)$$

Here $\tau_{\rm o}$ and $g_{\rm thin,o}$ are respectively the Sobolev optical thickness and the optically thin acceleration for a single,

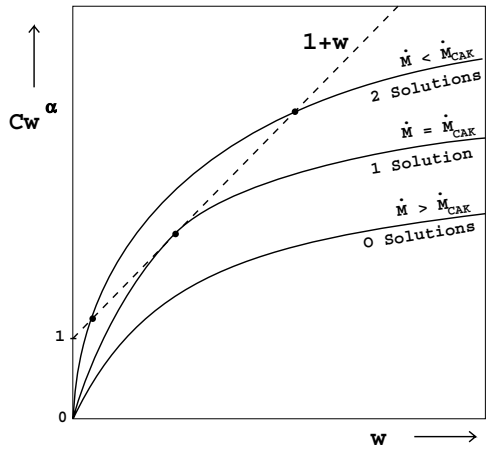

Figure 3. Graphical solutions of the dimensionless equation of motion (9).

spectral-peak line of opacity κ_o. This normalization opacity is given roughly by the line resonance amplification factor discussed previously,

$$\frac{\kappa_o v_{th}}{c} \approx \bar{Q}\kappa_e \approx 10^3 \kappa_e$$

which thus implies that $g_{thin,o} \approx 10^3 g_e$, as noted earlier. In this context, $\bar{Q}$ can be thus thought of an alternative, dimensionless way to specify the opacity normalization.

Ignoring the generally unimportant contribution of gas pressure, the steady-state equation of motion simply requires that the wind acceleration must equal the line acceleration minus the inward acceleration of gravity,

$$v\frac{dv}{dr} = g_{cak} - \frac{GM(1-\Gamma_e)}{r^2}$$

wherein we have also taken into account the effective reduction of gravity by the free-electron scattering factor Γ_e.

Defining the flow acceleration in units of the gravity as

$$w \equiv r^2 v v' / GM(1-\Gamma_e)$$

the equation of motion can be rewritten in the simple, dimensionless form,

$$w = C\, w^\alpha - 1 \qquad (9)$$

where the constant is given by

$$C = \left(\frac{\bar{Q}\Gamma_e}{1-\Gamma_e}\right)^{1-\alpha} \left(\frac{L}{\dot{M}c^2}\right)^\alpha .$$

Figure 3 illustrates the graphical solution of this dimensionless equation of motion for various values of the constant C. For fixed stellar and opacity distribution parameters, this corresponds to assuming various values of the mass loss rate $\dot{M}$. For high $\dot{M}$ there are no solutions, while for low $\dot{M}$ there are two solutions. The two limits are separated by a critical case with one solution—corresponding to the *maximal* mass loss rate—for which the function Cw^α intersects the line $1 + w$ at a tangent. For this critical case, the tangency requirement implies $\alpha C_c w_c^{\alpha-1} = 1$, which together with the original equation (9) yields the critical conditions $w_c = (\alpha/1-\alpha)$ and $C_c = 1/(\alpha^\alpha(1-\alpha)^{1-\alpha})$.

Since equation (9) has no explicit spatial dependence, these conditions hold at all radii. By spatial integration of the critical acceleration w_c from the surface radius R_*, we thus obtain the CAK velocity law,

$$v(r) = v_\infty \left(1 - \frac{R_*}{r}\right)^{1/2} \qquad (10)$$

where the terminal speed is given by $v_\infty = v_{esc}[\alpha/(1-\alpha)]^{1/2}$, where v_{esc} is the effective surface escape speed. Likewise, the associated critical value of C_c defines the maximal CAK mass loss rate

$$\dot{M}_{cak} = \alpha \left(\frac{(1-\alpha)\bar{Q}\Gamma_e}{1-\Gamma_e}\right)^{(1-\alpha)/\alpha} \frac{L}{c^2}. \qquad (11)$$

Comparison with equation (7) shows that the first two factors in equation (11) now provide an explicit expression for the number of thick lines.

These results strictly apply only under the idealized assumption made above that the stellar radiation is radially streaming from a point source. If one takes into account the finite angular extent of the stellar disk, then the mass loss is slightly reduced (typically by about a factor of 2), and the velocity law becomes slightly flatter (approximated by replacing the exponent 1/2 in equation (10) by a value $\beta \approx 0.8$), with a somewhat higher terminal speed ($v_\infty \approx 3v_{esc}$).

Finally, another simplifying assumption of this analysis is that the line opacities are spatially constant, which implies a fixed wind ionization. The effect of a radial change in ionization can be approximately taken into account by correcting the CAK force (8) by a factor of the form $(n_e/W)^\delta$, where n_e is the electron density, $W \equiv 0.5[1-(1-R_*/r)^{1/2}]$ is the radiation 'dilution factor', and the exponent has a typical value $\delta \approx 0.1$. This factor introduces an additional density dependence to that already implied by the optical depth factor $1/\tau_o^\alpha$ given in equation (8). Its general effect on the mass loss can be roughly accounted with the simple substitution $\alpha \to \alpha' \equiv \alpha - \delta$ in the power exponents of the CAK mass loss scaling law (11). The general tendency is to moderately increase $\dot{M}$ and accordingly to somewhat decrease the wind speed.

The wind momentum–luminosity relation

An important success of these CAK scaling laws is the theoretical explanation they provide for an empirically observed 'wind momentum–luminosity' (WML) relation. Combining the CAK mass loss law (11) together with the

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

scaling of the terminal speed v_∞ with the effective escape speed $v_{\rm esc} = [2GM(1-\Gamma)/R]^{1/2}$, we obtain a WML relation of the form,

$$\dot{M} v_\infty R_*^{1/2} \sim L^{1/\alpha'} Q^{1/\alpha'-1}$$

wherein we have neglected a residual dependence on $M(1-\Gamma)$ that is generally very weak for the usual case that α' is near 2/3. Stellar mass loss rates can be routinely derived by fits to the observed Balmer (Hα) line emission, and wind terminal speeds can be inferred from the blue edge of observed P-Cygni profiles. Combined with spectroscopic estimates of the stellar luminosity and radius (the latter of which in any case enters only weakly as a square root), empirical fits for a large sample of galactic OB supergiants have demonstrated a remarkably tight agreement with a single WML relation. These fits give a luminosity slope that implies $\alpha' \approx 0.57$ and an overall normalization that is quite consistent with the expectation that $\bar{Q} \approx 10^3$.

Less extensive fits have also been derived for OB stars in the Magellanic clouds. These are each separately consistent with a single WML relation, but with a lower normalization, especially for the small cloud. This probably just reflects the weaker radiative driving from the lower metallicity Z, since the line opacity normalization varies in direct proportion to the metallicity, $\bar{Q} \sim Z$. There are currently efforts toward carefully calibrating this WML relation and its dependence on metallicity. The ultimate goal is to apply observationally inferred wind parameters of luminous hypergiant stars in external galaxies as an alternative 'standard candle' for extragalactic distance measurements. In this way hot-star winds may play a role in calibrating the distance scale of the universe.

The Wolf–Rayet wind 'momentum problem'

WR STARS are evolved, massive, hot stars for which the cumulative mass loss has led to depletion of the original hydrogen envelope. They typically show broad wind emission lines of elements such as carbon, nitrogen and/or oxygen that are the products of core nucleosynthesis. Overall, observations indicate that WR winds are especially strong, and even optically thick to continuum scattering by electrons. Notably, inferred WR wind momenta $\dot{M} v_\infty$ are generally substantially higher than for OB stars of comparable luminosity, placing them well above the OB star line in the WML relation. In fact, the inferred ratio of the wind momentum to that of stellar luminosity, $\eta \equiv \dot{M} v_\infty/(L/c)$, is typically much above unity, sometimes as high as $\eta = 10$–50.

This last property has generally been cast as the WR wind 'momentum problem', sometimes with the implication that it implies that WR winds cannot be radiatively driven. In fact, it merely means that, unlike for OB stars, WR winds cannot be treated in the standard, single-scattering formalism, which assumes optically thick lines do not overlap within the wind. However, momentum ratios above unity can, in principle, be achieved by multiple scattering between overlapping

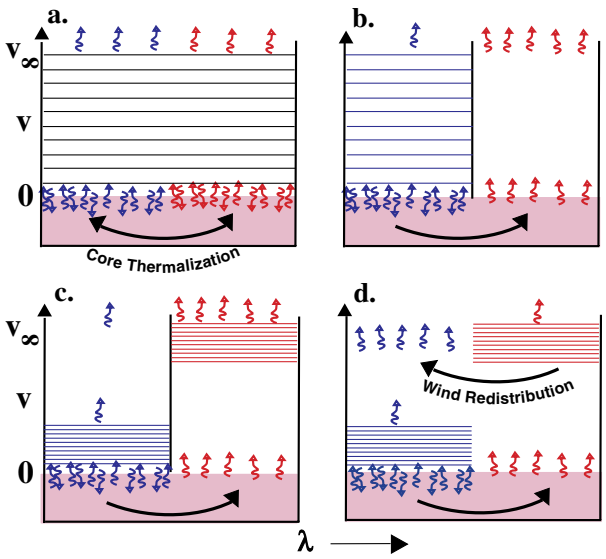

Figure 4. Schematic diagram illustrating the role of line gaps, line bunches and photon thermalization for WR wind momentum deposition. The horizontal lines represent the velocity–frequency spacing of optically thick lines in the wind. The four parts represent (*a*) an effectively gray model, (*b*) a wind with fixed ionization and extensive gaps, (*c*) a wind with ionization stratification that fills gaps and (*d*) the importance of limiting energy redistribution in the wind.

thick lines with a velocity unit frequency separation $\Delta v < v_\infty$. Indeed, if the spectral distribution of lines is 'gray'—i.e. spread randomly through the spectrum without substantial gaps or bunches—then the momentum attained scales simply with the mean thick-line velocity separation as $\eta \approx v_\infty/\Delta v$ (figure 4(*a*)).

However, realistic line lists are not gray, and leakage through gaps in the line spectral distribution tends to limit the effective scattering to $\eta \lesssim 1$ (figure 4(*b*)). However, the optically thick nature of the WR winds gives them a substantial ionization stratification, and this helps to spread line bunches and so fill in gaps, allowing for more effective global trapping of radiation that makes $\eta > 1$ (figure 4(*c*)). Redistribution of photon energy can reduce the local effectiveness of line driving (figure 4(*d*)). In particular, redistribution by photon thermalization near the stellar core makes it especially difficult for radiation alone to initiate the wind. The relative complexity of WR wind initiation may be associated with the extensive turbulent structure inferred from observed variability in WR wind emission lines. Overall, the understanding of WR winds is perhaps best viewed as an 'opacity problem', i.e. identifying the enhanced opacity that can adequately block the radiation flux throughout the wind and thus drive a WR mass loss that is much greater than from OB stars of comparable luminosity.

Wind instability and variability

There is extensive evidence that hot-star winds are not the smooth, steady outflows idealized in the simple

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

CAK theory but rather have extensive structure and variability on a variety of scales. The most direct example is the explicit variability often detected in unsaturated absorption troughs of P-Cygni line profiles. To produce such explicit line profile variability, the associated wind structure must be relatively large scale, covering a substantial fraction of the stellar disk. (By comparison, the emission component of P-Cygni profiles is generally much less variable, since it forms from a more global average of the wind.)

Much of the variability can be characterized as 'discrete absorption components'. These begin as broad absorption enhancements in the inner part of the blue absorption trough of an unsaturated P-Cygni line, which then gradually narrow as they drift, over a period of days, toward the blue edge of the profile. Their occurrence is generally irregular, and their apparent acceleration is quite slow, much slower than expected for an element of the steady wind. They may reflect the slow acceleration of mass ejected by some kind of semirandom disturbance from the underlying stellar surface. The exact nature of this is unknown, but might possibly be linked to either magnetic activity or stellar pulsation.

In a second class of explicit variation are the 'periodic absorption modulations'. These occur at regular, sometimes multiple periods, and include both a modulated increase and decrease in the absorption strength. The periods are generally of order a few days, which is consistent with a low-order multiple of the stellar rotation period. They probably represent rotational modulation of wind structure by an unknown kind of surface irregularity (again perhaps magnetic).

The optical emission lines formed in WR winds also commonly show a low- amplitude variability. Such optical lines have been monitored using ground-based telescopes at much higher signal-to-noise ratio than has been typical for the ultraviolet wind lines monitored from OB stars by orbiting satellites. Analysis suggests a turbulent hierarchy of structure extending down to quite small spatial scales.

There is also indirect evidence that OB winds have an extensive, small-scale, turbulent structure. Saturated P-Cygni lines have extended black troughs thought to be a signature that the wind velocity is highly nonmonotonic. Such stars commonly show soft x-ray emission and sometimes also nonthermal radio emission, both of which are thought to originate from embedded wind shocks.

A promising explanation for this small-scale, turbulent structure is the intrinsically strong instability of line driving to small-scale velocity perturbations. As noted above, there is a strong hidden potential in line scattering to drive wind material with accelerations that greatly exceed the mean outward acceleration. Numerical simulations suggest this can indeed lead naturally to a highly structured flow dominated by multiple shock compressions. However, it is not yet clear whether the simulated flow properties can robustly explain key observational features such as the soft x-ray emission.

Frontiers: colliding winds, disks, etc

The theory for line-driven winds is mature enough that it is now finding application in many more complex circumstances. Let us thus briefly summarize some of these frontiers.

One example is colliding winds of close, massive star binaries. In several cases these involve WR + O stars with separations of only a few O-star radii. Generally the WR wind is so much stronger that a simple hydrodynamic ram balance between the two stars is not possible. This suggests the WR wind should simply overwhelm its companion's outflow and penetrate down to the O-star surface. Orbital phase monitoring of such systems suggests, however, that this does not occur, but that a wind–wind interface is generally kept away from the O-star surface. An attractive explanation for this comes from considering the additional pressure provided by the O-star light in a *radiative braking* of the impacting WR wind. Such a radiative deceleration has many of the same properties of the usual wind acceleration, including a crucial role for the Doppler shift of line resonance in allowing a strong line force. An interesting result is that radiative braking is generally only effective if the interaction of O-star light with WR material is characterized by a stronger line opacity than needed for driving the O-star wind. This represents a new twist to the usual 'opacity problem' of how WR stars drive such strong winds and even suggests that observations of WR + O binaries could help to constrain answers to this fundamental question.

Hot stars generally have a rapid rotation, but among the fastest rotators are the BE STARS, which are characterized by strong Balmer line emission thought to originate in a circumstellar disk. A quite appealing idea is that these form naturally as 'wind-compressed disks' by rotational focusing of the star's radiatively driven stellar wind toward the equatorial plane. Initial dynamical simulations that assumed a simple, radial form for the line force generally supported this idea. Surprisingly, however, subsequent, more realistic models show that *nonradial* components of this line force can actually completely *inhibit* the formation of such a disk by effectively driving material away from the equatorial plane. Further analysis has shown how this, and other peculiar properties of line driving, follows naturally from the characteristic scaling of the line force with the velocity gradient.

Finally, line-driven winds can also originate from luminous accretion disks, such as those found in cataclysmic variables (see also CATACLYSMIC BINARIES: CLASSICAL AND RECURRENT NOVAE). Recent work has thus focused on extending the basic CAK theory to account for key differences from the stellar case, for example the 2D nature of the flow and the peculiar nonmonotonic variation of the effective gravity, which initially increases from the disk plane before eventually falling off with distance. There is even renewed interest in developing such disk wind models to explain the broad-line flows observed from ACTIVE GALACTIC NUCLEI and QUASARS.

Bibliography

The theory of hot-star winds is nearly three decades old, and in this time there has amassed an appropriately large literature.

The basic notion of line driving was first broached in a prescient paper by

Milne E A 1926 *Mon. Not. R. Astron. Soc.* **86** 459

The seminal work laying out the CAK formalism still used today was in

Abbott D 1982 *Astrophys. J.* **263** 723
Castor J I, Abbott D C and Klein R I 1975 *Astrophys. J.* **195** 157

The key Sobolev approximation was developed in

Sobolev V V 1960 *Moving Envelopes of Stars* (Cambridge, MA: Harvard University Press)

The reformulation of the CAK scalings in terms of the Q of line resonances was by

Gayley K G *Astrophys. J.* **454** 410

A key paper testing the validity of the Sobolev approach was also one of the first to relax the CAK point-star approximation:

Pauldrach A, Puls J and Kudritzki R 1986 *Astron. Astrophys.* **164** 86

Wind variability is the subject of several recent conference proceedings:

Kaper L and Fullerton A (eds) 1998 *Cyclical Variability in Stellar Winds* (Dordrecht: Kluwer)
Moffat A, Owocki S, St-Louis N and Fullerton A (eds) 1994 *Instability and Variability in Hot Star Winds* (Dordrecht: Kluwer)
Wolf B, Fullerton A and Stahl O (eds) 1999 *Variable and Non-spherical Stellar Winds in Luminous Hot Stars (Springer Lecture Series in Physics)*

A recent paper on instability, which also addresses the general validity of the Sobolev approach, is

Owocki S P and Puls J 1999 *Astrophys. J.* **510** 355

WR stars have also been the subject of several recent conferences, with proceedings containing several reviews on the dynamics of WR winds both for single stars and in binary systems:

van der Hucht K, Koenigsberger G and Eenens P (eds) 1999 *Wolf–Rayet Phenomena in Massive Stars and Starburst Galaxies (IAU Symposium 143)* (Dordrecht: Kluwer)

Some general reviews on hot-star winds can be found in

Cassinelli J 1979 *Ann. Rev. Astron. Astrophys.* **17** 275
Howarth I (ed) 1997 *Boulder–Munich Workshop II* (San Francisco: Astronomical Society of the Pacific)
Kudritzki R and Hummer D 1990 *Ann. Rev. Astron. Astrophys.* **28** 303
Owocki S 1990 *Rev. Mod. Astron.* **3** 98
Puls J *et al* 1993 *Rev. Mod. Astron.* **6** 271

Finally, an essential general reference is the new introductory book on stellar winds:

Lamers H J G L M and Cassinelli J 1999 *Introduction to Stellar Winds* (Cambridge: Cambridge University Press)

Radio Emission from Binary Stars

Stellar radio emission is most common in double star systems where each star provides something essential in producing the large amounts of radio radiation needed for it to be detectable by RADIO TELESCOPES. They transfer mass, supply energy or, when one of the stars is a NEUTRON STAR or BLACK HOLE, have the strong gravitational fields needed for the energetic particles and magnetic fields needed for the radio emission process. However, while this is an area of science where we know what has been observed, the underlying causes are not well understood.

Radio emission from stars in general

Radio emission may be detected from either single or binary stars, although the latter are generally the most luminous. Because it is the closest star, the Sun is the brightest source of radio emission that we see produced by natural processes. This is mainly because it is so close. Other stars are 200 thousand times, or more, further away and, because the strength of observed radio emission weakens with the square of the distance, our Sun would appear about 40 billion times weaker if it were at the distance of the nearest star.

Only a small number of nearby single stars, called flare stars (see RED DWARFS/FLARE STARS), emit enough radio emission to be observable with the largest radio telescopes. Detecting the radio emission from stars usually requires physical conditions that produce stronger radio emission than is normal for stars. These extreme conditions occur most often when there are two or more stars in close orbits around each other. The strongest and most interesting radio emission comes when one star in a binary system is in its last stages of its life as a star.

BINARY STARS are common in the universe, but very few of them are detectable as sources of radio emission. This generally occurs under the special conditions where one of the companions either has an unusually high level of surface activity, or is a collapsed star at the end of its life. There are four types of special stars that are important for the strongest radio emission: 'normal' stars with much more surface activity than seen on the Sun; WHITE DWARF STARS, which are special because of their compactness and the sensitivity of their electron degenerate matter; neutron stars, which are special because of the neutron degeneracy of their matter and the stronger gravitational fields due to their compactness; and black holes, which are the most compact and massive 'dead' stars. White dwarfs, neutron stars and black holes are the final stages in the life of stars with masses in the range of 1–1.44 solar masses ($M_{\rm sun}$), (1–3)$M_{\rm sun}$ and $\geq 3\ M_{\rm sun}$, respectively. The extreme conditions of these dying, or dead, stars are important in producing strong radio emission.

Radio emission mechanisms

Radio emission, particularly from radio stars, comes from four basic processes involving some combination of radiating electrons and magnetic fields, with the latter needed for three of the most important processes.

The first process is thermal emission which arises because the temperature of the gas is hot enough so that interactions between electrons and the electrical field of protons in the gas, which must be in a partially or totally ionized plasma state, radiate by so-called braking radiation (bremsstrahlung). This form of radio emission limits the observed flux densities, the total emission that can be collected by a radio telescope, to

$$S_\nu \leq \frac{2kT_{\rm e}}{\lambda^2}\frac{\pi}{4}\left(\frac{D}{d}\right)^2$$

where k is Boltzmann's constant, $T_{\rm e}$ is the temperature of the electrons in the plasma, λ is the wavelength of observation by the telescope, D is the diameter of the source and d is the distance between the source and the observer. The maximum thermal emission occurs when the plasma is optically thick, that is, all radio photons are absorbed and re-emitted one or more times before escaping from the radiating plasma. Because ionized gases have temperatures that are generally either about 10 000 K or in extreme cases a million kelvins, this severely limits their radio emission. The non-thermal processes that have effective radiation temperatures from 10^8 to 10^{12} K are needed for most of the observed radio stars.

The next three processes differ from thermal emission only in that the emission is from electrons moving at a velocity v and interacting with large-scale magnetic field structures rather than the electric fields of protons. These three differ only in the energy of the radiating electrons. The lowest-energy electron–magnetic field radiation process is from electrons with Lorentz factors, $\gamma = 1/\sqrt{1-(v/c)^2}$, which are much less than 1; this is cyclotron or gyroresonance emission. The next highest energy process is gyrosynchrotron radiation where the electrons have $\gamma \sim 1$. The most important, and highest-energy, process, synchrotron emission, requires $\gamma \gg 1$ so the electrons are highly relativistic. Most radio stars are seen only because they have regions which produce highly relativistic electrons, moving very close to the speed of light, which then interact with large-scale magnetic field structures in the binary system or its outflows.

Need for acceleration of relativistic electrons

How nature can so easily produce highly relativistic plasmas is still a mystery that we only partly understand. We know that particle acceleration occurs in strong electric fields and in so-called reconnection events in magnetic field structures. However, the only process we believe can produce the needed highest-energy electrons is acceleration in shocks. Shocks occur whenever plasma or gas from different sources collides or interacts with each other, sometimes simply as internal structures in an extended plasma. The case where the matter ejected from a SUPERNOVA explosion collides with the interstellar medium is one reasonably well-understood process and is believed

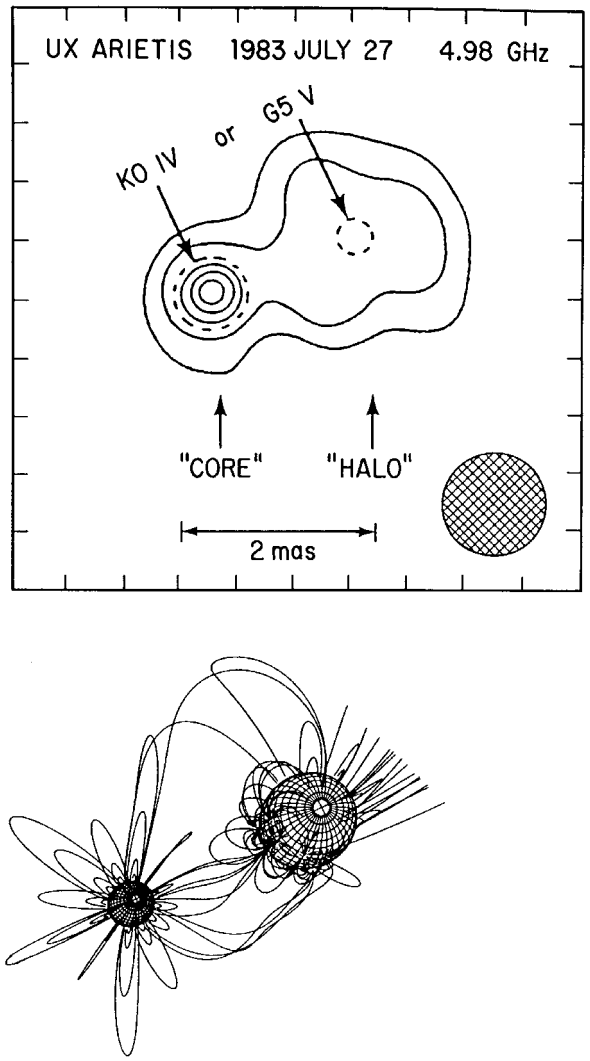

Figure 1. A VLBI image of the radio emission from the active binary UX Ari together with a drawing showing the active regions and magnetic field structures linking the two stars.

to supply most if not all observed COSMIC RAYS. In the cases of stars little is known about the shock interaction regions that produce the needed acceleration to highly relativistic energies. Observing strong radio emission is the main reason for believing that shocks accelerating relativistic electrons do exist in observed radio binaries.

Active binaries and flare stars

Nearby red dwarf flare stars were the first stars reported to have radio emission, although much of the early work is doubted because simultaneous monitoring for man-made radio interferences was not done. It was not until that was done, and interferometers less subject to interference were used in the 1970s, that stellar radio emission was definitely established. The radio emission from dwarf flare stars, called dMe stars because of their small size, M spectral type and characteristic occurrence of strong optical emission lines, is a scaled-up version of solar radio emission. The radiation is mainly from relativistic particles created by magnetic loop reconnection and other non-linear plasma phenomena. Many of the observed flare stars are in double star systems where both systems show radio emission. Active binaries where one star is a relatively cool K star with extreme magnetic surface activity are the greatest source of radio binaries involving normal stars. Figure 1 shows a radio image of the active binary UX Arietis together with a cartoon showing the probable magnetic fields linking the two stars.

It is generally believed, based on statistical evidence of their frequent occurrence, that active binaries are more active than equivalent single stars because one effect of having a companion star is the increase in the rotation rate of the active star. This rotation probably leads to increasing magnetic dynamo effects in convective regions near the outer layers of the stars, and this increases the number and size of large starspots and related magnetic activity leading to radio emission. It is still unclear whether intrastellar plasma phenomena are important in augmenting this activity or whether the regions between the stars are simply regions into which radio-emitting plasma, mainly radiating gyrosynchrotron emission, extends during magnetic activity.

Radio emission from white dwarf binaries

Binaries containing an evolved 'normal star' and a white dwarf produce episodic outbursts of optical, infrared and radio emission when shells of hot, ionized gas are ejected by thermonuclear explosions ocurring on the surface of the white dwarf. This happens when a companion star has expanded to fill its local gravitational (Roche) lobe and this transfers matter to the surface of the white dwarf. This increases the amount of non-degenerate matter on top of the degenerate electron material of the white dwarf. When this layer reaches roughly 1/10 000 of a solar mass, a thermonuclear explosion results and the non-degenerate, built-up layer is ejected at velocities of several hundreds to a few thousands of km s^{-1}. This is the cause of the NOVA, or 'new star' phenomenon, which is first seen by the sudden appearance of a bright, new star usually seen first by amateur astronomers. The nova shell is an ionized gas with temperatures near 10 000 K, and its thermal radio emission becomes observable in a few days or weeks when the size of the shell becomes large enough.

The radio emission from nova shells is first seen as optically thick surface emission, and with time the less dense outer layers become transparent, and more weakly emitting, as the opaque surface slowly moves from the outer part of the shell to the inner boundary of the shell. The resolved structure of the nova shells has been observed with large arrays of radio telescopes such as the Very Large Array in New Mexico and the Merlin array in England, the first being nova QU Vulpecula 1974 and the most recent being nova V1974 Cygni in 1992. These imaging

observations indicate shell masses higher than expected from theoretical models of the nova explosion process. Bright novae that are easy to study at all wavelengths occur only every several years.

Neutron star binaries and x-ray sources

Among the first stellar systems observed to show radio emission were strong x-ray sources such as SCORPIUS X-1 and CYGNUS X-1, which have these names because in the 1960s they were the strongest x-ray sources in their constellations. Sco X-1 is one of the class of radio-emitting binaries where a neutron star with a strong magnetic field and magnetosphere probably plays a major role in the process; Cyg X-1 was the first stellar system in our galaxy suspected of containing a black hole, and is in the class that we discuss in the next section.

In the early 1970s Sco X-1 would occasionally exhibit radio flares up to levels of 1/4 Jy that lasted a few hours; then it seemed to weaken in its flaring, only to return to 1/4 Jy level flaring in the late 1990s. Sco X-1 belongs to a small class of x-ray sources called Z-sources because of the Z-like shape they exhibit in plots where the ratio of the observed intensities at two high-energy ranges is plotted against the ratio of intensity for two lower-energy ranges. The Z-sources at any one time occupy only one location in their Z-diagram and this identifies the state of the X-ray source. The properties of these sources, including their radio emission, vary in the Z-diagram. Sco X-1 and other Z-sources such as Cygnus X-2, GX17+2 and GX349+2 show the weakest and most steady radio emission when at the lower end of the Z and have stronger and more erratically variable radio sources as the sources move to the other end of the Z.

At the time of this writing we can only speculate that the weak steady emission may be due to jet-like radio emission while the stronger, more erratic emission is related to complex, flare-like phenomena arising from the magnetospheric regions generated by the neutron stars. One could also speculate that some of the unusual radiation processes seen in single neutron stars seen as radio pulsars, may occur in a weaker and non-periodic form in X-RAY BINARIES containing neutron stars.

There are a number of other radio-emitting star systems where a neutron star component is probably involved. One is the periodically flaring system LSI $+61^\circ$ 303, which is an x-ray binary with a period of 29 days, where the compact star is moving inside the strong stellar wind from its companion star with what is probably an elliptical orbit. In this system it is believed that when the compact star is closest to the other star radio flaring is initiated, perhaps because of the strengthening of the bow shock region where the winds from the compact star's ACCRETION DISK interact with the wind of the other star. Circinus X-1 is a similar case where radio flaring is triggered once in each orbit of the compact star around its companion. The neutron star binaries Aquila X-1 and Centaurus X-4 have been shown to exhibit radio flares associated with recurring x-ray outbursts.

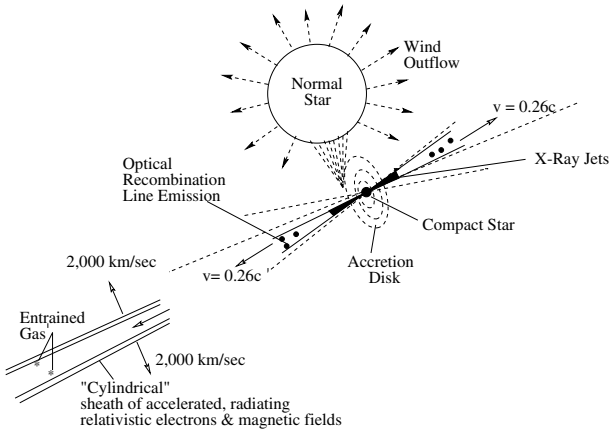

Figure 2. A cartoon showing the x-ray, optical and radio-emitting jets of SS433. They are ejected along the axis of the accretion disk at a velocity of 0.26*c*.

There are two binary systems where the evidence is not clear whether the compact star is a neutron star or a black hole: Cygnus X-3 and SS433. Because black hole binaries seem to show stronger radio events than neutron star binaries, we will discuss Cygnus X-3 and SS433 with the black holes and black hole candidates.

Binary stars with black holes and black hole candidates

In the late 1970s the 433th entry in the Stephenson–Sandeulek catalog of emission line stars, called SS433 (figure 2), was found to show a strong 162.5 day periodicity in the velocities of its optical emission lines which indicated jets of emission with velocities of 26% of the speed of light, or 0.26*c*. That this was due to precession of jets ejected along the rotational axis of the accretion disk was verified when x-ray emission lines and images of radio emission were seen to show changes explainable by a precessing jet. The x-ray and optical lines vary with radial velocity along the line of sight, with a stationary line system, one line system producing emission with redshifts indicating that they are moving away from us and another line system with the blueshifts of material moving toward us. The radio emission is seen in radio images on size scales ranging from a few milliarcseconds up to several arcseconds and exhibits lateral proper motions that provide us with the full three-dimensional picture of the behavior of the 0.26*c* jets. It is still uncertain whether SS433 is a binary with a neutron star or a black hole. Depending on which evidence in emphasized the conclusion can go either way. However, although SS433 seemed to be unique for 15 yr, the phenomenon of highly relativistic radio jets has recently been shown to be associated with some binary systems that are either clearly established or strongly suspected to be binary stars with black hole systems.

The discovery of highly relativistic radio jets in the recurring but transient x-ray binaries GRS 1915 + 105, GRO J1655-40 and XTE J1748-288 in 1994, 1994 and 1998,

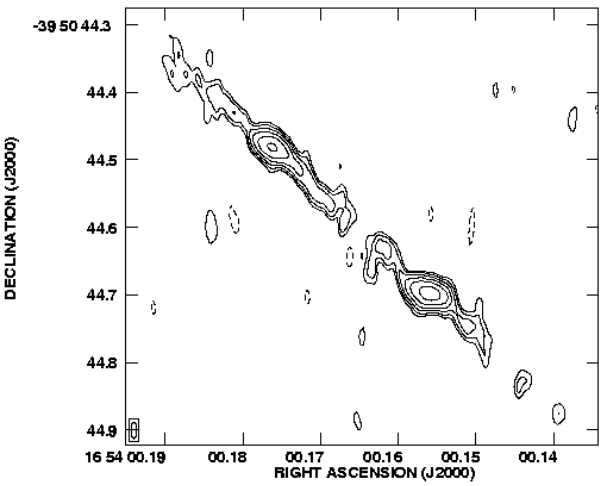

Figure 3. An 18 cm VLBA radio image of GRO J1655-40 made on 18–19 August 1994 showing its jets, which appear superluminal on one side. The brightest region at the lower right is the location of the black hole x-ray binary and the material to the upper left is moving with an apparent lateral velocity of $1.1c$ owing to relativistic effects resulting from its $0.92c$ velocity.

respectively, brought the realization that strong radio flares are often associated with the x-ray events where highly relativistic radio jets are ejected with velocities near the speed of light. These three systems show apparent motions of radio-emitting matter moving towards us that seem to be moving faster than the speed of light. The finiteness of the speed of light causes the radio emission seen at a particular time to be emitted earlier from the far side jet and later from the near side jet such that the apparent velocities are

$$v_{\text{apparent}} = \frac{v}{1 \pm (v/c)\cos(\Theta)}$$

where the + sign is for the receding jet, the − sign is for the aproaching jet and Θ is that angle between the line of jet ejection and the line of sight to an observer. For the three superluminal jet sources, v_{apparent}/c is 1.4, 1.1 and 1.3, respectively. It is because v/c is close to unity in these systems that it is possible for the denominator in this equation to become small, leading to $v_{\text{apparent}} > c$ and producing a so-called superluminal jet source. Superlumiminal jets are commonly present in extragalactic systems such as quasars and active galactic nuclei.

Figure 3 shows the high-resolution radio image of GRO J1655-40 observed with the Very Long Baseline Array (VLBA) on 18–19 August 1994, about a week after this black hole binary ejected a jet with a velocity of $0.92c$. The binary x-ray source is located in the middle of the central bright source in the lower right and the material to the upper left is the approaching jet moving with an apparent velocity of $1.1c$. It has been established that the GRO J1655-40 binary system consists of a 7 solar mass black hole orbiting around a 1.2 solar mass F2 IV star every 2.61 days. Matter from the F2 IV star falls toward the black hole forming an accretion disk whose inner regions are disappearing into the event horizon of the black hole. The x-ray outburst associated with the relativistic jet ejection in early August 1994 was the result of a state change in the black hole's disk of accreting matter when it went from weakly to strongly radiating in x-rays, with the ejection of the observed radio jet along the rotation axis of the accretion disk.

SS433, GRS1915 + 105, GRO J1655-40 and XTE J1748-288 all exhibit another effect due to the relativistic nature of their jets: Doppler boosting, due to the relativistic distortion of the area of the emitting regions as seen by a distant observer, so the apparent ratio of the flux density of the approaching and receding jets is given by

$$\frac{S_{\text{approaching}}}{S_{\text{receding}}} = \left(\frac{(1 + (v/c)\cos(\Theta)}{1 - (v/c)\cos(\Theta)}\right)^{k-\alpha}$$

where α is the spectral index of the radio emission and $k = 2$ or 3 depending on whether the jet is continuous or blob like.

The x-ray binary Cygnus X-3 is the system with the most frequent, strong radio flares, exhibiting an average of two big flares per year since first discovered in 1972. In early 1997 an 11 Jy flare in Cyg X-3 was imaged at very high resolution, showing an entirely one-sided jet with $v \geq 0.8c$ and $\Theta \leq 8^{\circ}$. The Doppler boosting of the Cyg X-3 jets pointing nearly at the Earth is part of the reason why Cyg X-3 flares are so strong, often rivaling the apparent radio brightness of distant QUASARS. These systems with highly relativistic jets are frequently described as microquasars.

Future prospects

The study of radio events in binary stars with one stellar component having magnetic-field-driven surface events, or being a compact white dwarf, neutron star or black hole, is one of the best ways to study relativistic plasma outflows in stars. With X-RAY ASTRONOMY satellites monitoring the sky for x-ray outbursts, astronomers can quickly turn x-ray, radio and infrared or optical telescopes to observe these objects with their accretion disks and outflows that develop synchrotron radio emitting plasmas. Arrays of radio telescopes such as the Very Large Array, the Westerbork Synthesis Radio Telescope, the Australian Telescope Compact Array, the VLBA, the European VLBI Network, the Giant Metre-wave Radio Telescope and other arrays of radio telescopes promise to continue generating images detailing the evolution of these relativistic plasma events. These images, when combined with x-ray, optical and infrared information about the events, will continue to play a major role in the study of the major events in exotic binary star systems.

Radio Galaxy

A galaxy that is an intense source of radio-frequency emission. The radio luminosity of a strong radio galaxy (10^{37}–10^{39} watts) can be up to a million times greater than the radio output of a conventional galaxy (typically about 10^{33} watts) and up to a hundred times greater than the optical luminosity of a galaxy such as the Milky Way. The optical counterparts of radio galaxies are usually elliptical galaxies

In a typical radio galaxy, most of the radio emission comes from two 'lobes' (clouds of radio-emitting material), often located beyond and on either side of, the visible galaxy. Typically, the radio-emitting clouds span a region of space five to ten times larger than the optical galaxy. The overall extent of a radio galaxy (measured across its lobes) may be several million light-years; indeed, the lobes of the giant radio galaxy 3C 236 ('3C' denotes the Third Cambridge Catalogue of radio sources) have an overall diameter of nearly 20 million light-years. High-resolution images show that many radio galaxies also possess a compact central radio source from which there emerges a jet, or a pair of oppositely directed jets, of radio-emitting material, pointing outwards towards the distant lobes. The radio-emitting lobes are believed to be clouds of electrically charged particles (predominantly electrons) that have been expelled at some time in the past, from a central 'powerhouse' in the core of the galaxy. The jets appear to be streams of highly energetic electrons that have been accelerated to a substantial fraction of the speed of light. Spots of enhanced intensity are often seen where the outflowing jets of particles plough into the distant lobes.

The jet and lobes radiate synchrotron radiation (a type of radiation that is emitted by charged particles traveling at large fractions of the speed of light in magnetic fields). The spectrum of a radio galaxy is relatively 'flat', displaying the smooth slow decline in intensity from low to high frequencies (from long to short wavelengths) that is typical of a synchrotron source (by contrast, the spectrum of a galaxy like the Milky Way is dominated by the combined light of its constituent stars and, like that of a star, rises steeply at the short-wave end of the spectrum, reaches a peak in the visible and declines in the infrared).

The energy that is needed to produce the lobes and sustain them for tens of millions of years is very substantial; in the region of 10^{53} joules for a strong radio galaxy. The 'energy machine' that is responsible for ejecting the lobes and powering the jets is believed to reside in the core of the galaxy and is widely considered to be a supermassive black hole surrounded by an accretion disk of heated gas.

The first radio galaxy to be identified was Cygnus A, a classic double-lobed strong radio galaxy. The nearest (rather weak) radio galaxy, Centaurus A, lies at a distance of about 15 million light-years.

Radio Instrumentation

RADIO TELESCOPES generally fall into two categories: single-dish telescopes, where one antenna is used on its own as a telescope, and synthesis arrays or INTERFEROMETERS, where several antennas are combined to synthesize the effect of one very large telescope. Whilst instrumentation on a single-dish radio telescope can often be changed in a similar way to that on an optical telescope, instrumentation on a synthesis array tends to be very tightly integrated into the telescope system. In this article, instrumentation for the two classes of radio telescope is therefore considered separately.

Single dish continuum detectors

The earliest radio telescopes worked in a simple 'single dish' mode, in which the entire signal of the telescope was focused on to a single detector. This detector was typically a low-noise amplifier followed by a detector that simply measured the amount of continuum radio power falling onto it. Much of the early pioneering work of radio-astronomy was performed with this simple arrangement. To make an image of the source, it was necessary to move the entire telescope back and forth in a raster pattern, and thus gradually build up a radio image of the area being surveyed. In practice, this raster pattern was generally composed of a number of points set in a rectangular grid. The telescope would be pointed at each of these grid points in turn, and a total power measured. However, this technique is limited by fluctuations in the receiver power caused either by the atmosphere or by the electronics. A modern variant of this technique is 'on-the-fly' mapping, where the telescope is kept in constant motion. As a result, fluctuations in receiver power due to atmosphere or electronics occur on a longer timescale than the observed changes in power caused by the motion of the telescope beam past a radio source in the sky, and so the two effects can be separated out. Thus, on-the-fly mapping yields more reliable images than the earlier gridded images.

The main limitation of the technique of using a single dish for continuum imaging of the sky is the relatively poor spatial resolution obtainable with a single-dish telescope. However, this simple single-dish technique is still sometimes used for specialist purposes, particularly at millimeter and sub-millimeter wavelengths where receivers tend to be too complex to build in multiple packages (see RADIO TELESCOPE DATA PATH FOR SINGLE DISH AND INTERFEROMETERS).

Modern radio-astronomy RECEIVERS come in two varieties. The most common is a heterodyne receiver, in which the incoming signal is successively amplified and mixed with local oscillators to produce a coherent signal at low frequency which can then be processed in 'back-end' instrumentation. At millimeter and sub-millimeter wavelengths, the receiving element is sometimes a bolometer, which is a sensitive device that measures the instantaneous incoherent radio power falling on the detector.

Spectroscopy

In the early days of radio-astronomy, measurements of the radio spectrum of a source were made by using a set of filters, each tuned to a slightly different frequency. Such an instrument was used in many early pioneering studies of the neutral hydrogen line. However, it suffered both from instability in the electronics and from a relatively limited frequency resolution.

In the 1970s, Fourier transform or autocorrelation spectrometers (or 'CORRELATORS') were developed. In these instruments, a signal was successively delayed electronically in a shift register, and then the delayed samples were then cross-correlated with the original signal. The resulting autocorrelation function was then Fourier transformed to produce a spectrum of the signal. This technique was not possible until the advent of fast digital computers to perform the Fourier transform, but once established it quickly replaced the older filter banks. Its advantages were much higher stability and flexibility, and a scalability which allowed very high frequency resolution. In recent times, correlators with up to one million channels have been produced for specialist projects such as that of the SETI INSTITUTE.

Until recently, these autocorrelation spectrometers still suffered from a relatively low total bandwidth, which was limited by the speed of the available electronic components. This bandwidth was generally too low for millimeter work, and so a different type of spectrometer was born. This was the acousto-optic spectrometer (or AOS) which was widely used at millimeter and submillimeter telescopes. In this type of spectrometer, the radio signal is applied to a Kerr cell, causing a periodic modulation of opacity across the Kerr cell. A laser beam applied to this Kerr cell is diffracted by the resulting grating, and the intensity distribution of the diffracted laser beam is effectively the Fourier transform of the input signal, and thus gives the spectrum of the input signal. Such a spectrometer can cover a very wide bandwidth (up to several GHz), but suffers from a high sensitivity to thermal instability, so that these spectrometers need elaborate calibration schemes to be usable for radio-astronomy. They have recently started to be supplanted by autocorrelation spectrometers, since the advent of high-speed samplers has meant that autocorrelation spectrometers can now operate up to bandwidths of several GHz.

Pulsar timing

Specialist receivers are used to search for and study PULSARS. These receivers differ from conventional ones both in their ability to combat interstellar DISPERSION and in their ability to record data in 'bins' of short time duration (see PULSAR BACKENDS).

In pulsar searches, it is necessary to record data at a very high rate, as the data need to be sampled at millisecond intervals with a wide bandwidth. This typically results in tens of gigabytes of data per day of observation. These data are then analyzed offline using

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

powerful but computationally expensive algorithms that search for periodicities in the data (see SOFTWARE: RADIO PULSAR SOFTWARE).

For studying the characteristics and timing of known pulsars, the data rates can be much lower as the data can be synchronously added into a number of 'bins', each covering a small (millisecond) time interval across the pulsar period. The data may then be integrated over a period of minutes, and at the end of this integration only an amplitude for each bin need be recorded.

In all studies of pulsars, allowance must be made for the dispersion of the pulsar signal as it passes through the interstellar medium. This dispersion occurs because high-frequency radio waves travel faster through an ionized medium than low-frequency waves. So, a sharp pulse emitted by the pulsar will be blurred out over time, and if no correction is made for this effect, the pulse recorded back on Earth using a wide bandwidth will be weakened and broadened. To correct for this, 'de-dispersers' are used, in which the received band is broken into a number of small frequency channels using either a filter bank or a correlator, in the same way as for spectroscopy, as described above. The signals in the different channels are electronically delayed by an appropriate amount such that the pulses in all channels are once more aligned in time. The data from all the channels can then be integrated together. Recently, the increasing power of high-speed electronics and computers has enabled an additional technique to be used, in which the raw signal from the telescope is recorded as a voltage at very high speed (at hundreds of millions of samples per second). Then all these corrections to the data can be made off-line on high-speed computers at the same time as other processing.

Multibeam and array feeds

Traditional single-dish radio-astronomy typically uses just one or two receiving elements at the focus of the telescope. Increasingly, there is pressure to mount an array of receiving elements at the focus. This evolution is similar to the replacement of photomultipliers on optical telescopes by ccd arrays. However, the challenge is harder at radio wavelengths because the physical size and the complexity of the receivers makes it difficult to mount more than one receiver at the focus simultaneously. However, a feed array with n elements increases the power of the telescope by a factor of n, and so the pressure to develop such multibeam receivers is huge. At millimeter wavelengths, the physical size of the receivers does not present such a problem as those operating at longer wavelengths, and so the first experimental multibeam receivers, developed at several observatories, typically had a few elements and operated at millimeter wavelengths.

However, the first multibeam receiver to make a major impact on radio-astronomy was the seven-beam receiver developed by NRAO and successfully deployed first on the GREENBANK 70 m telescope in the USA and then on the PARKES OBSERVATORY 64 m telescope in Australia. It was used to make a very successful continuum survey of the entire sky at a wavelength of 6 cm.

In 1997, a 13-beam receiver operating at 21 cm was mounted on the Parkes 64 m telescope, representing a milestone in radio-astronomy instrumentation. This receiver, which required a major upgrade of the telescope in order to accommodate its enormous size, was used for both spectroscopic surveys of neutral hydrogen and for pulsar searches.

At millimeter wavelengths, development of array feeds is continuing, using both heterodyne receivers and bolometers. A major advance was signalled by the development of SCUBA (Submillimeter Common-User Bolometer Array) which was installed on the James Clerk Maxwell Telescope in 1996. SCUBA consists of two arrays of bolometers, containing 37 and 91 elements respectively. Plans are already being made for similar receivers with an even larger number of elements.

Another type of array feed which is in its early stages of development is the focal plane array in which the focal plane is sampled sufficiently densely to be able to measure the electric field across the focal plane. The signals from the different elements are cross-correlated, and the Fourier transform of the cross-correlation function yields a holographic image of the electric field distribution across the telescope. Corrections can then be made to this image for effects such as telescope deformation, pointing errors and atmospheric effects. In principle, this technique can yield a near-perfect image of the sky, regardless of the quality of the telescope or the atmosphere.

Synthesis arrays and interferometry

All the types of instrumentation fitted to single-dish radio telescopes, with the exception of the bolometer, can also be fitted to radio synthesis arrays or interferometers. In practice, because each instrument generally has to be duplicated many times over, synthesis arrays usually have far less flexibility than single-dish radio telescopes, and so the range of instrumentation tends to be smaller.

Modern synthesis arrays all use correlators to combine the data from their telescopes, and these correlators follow the same principles as those correlators used for spectroscopy in single-dish radio-astronomy. Thus, the two functions are relatively easily combined, so that a synthesis array can generally yield images in each of many frequency channels across the observing band. In practice, the size of the correlator tends to be limited, and so older instruments such as the VERY LARGE ARRAY tend to have only a modest spectroscopic capability, whereas more recent instruments tend to have much higher spectroscopic resolution. Similarly, the correlators on synthesis arrays can be designed to include 'binning' for pulsars, and several instruments offer this capability for pulsar astronomy.

In very long baseline interferometry (VLBI), the same principles apply, and most VLBI correlators offer both a spectroscopic mode and a pulsar binning mode.

The future

Instrumentation on radio telescopes is changing rapidly on several fronts. Increasingly, the distinction between on-line instrumentation and off-line processing is becoming blurred.

For example, the increasing speed and power of general-purpose computers means that some functions that once had to be performed in hardware can now be done in software. One example, mentioned above, is the class of pulsar search and de-dispersion techniques, which is now within the reach of general-purpose computers.

Another aspect of this blurring is the move towards real-time processing. At present, data from a synthesis array are typically collected over a period of hours, then written to tape or CD-ROM, and then taken back to a user's institution for analysis. However, the amount of processing time needed is now typically smaller than the observing time, and so this processing is starting to be performed in real-time on computers attached to the on-line system.

Another change that is rapidly occurring is the increase in radio-interference contamination of radio-astronomy signals. There are two causes of this. One is the rapidly growing rise in interference that occurs within supposedly protected radio-astronomy bands. For example, the designated 18 cm radio-astronomy bands are becoming very badly contaminated by out-of-band emissions from constellations of low-Earth orbiting satellites. The other cause of the problem is the need for radio-astronomers to receive radiation from a greater fraction of the available spectrum than that officially designated as a radio-astronomy protected band. For example, technology now allows us to study the neutral hydrogen emission from GALAXIES AT HIGH REDSHIFT. The redshifted hydrogen lines fall well outside the band protected for radio-astronomers.

To enable radio-astronomy to continue in the face of this interference, it is clear that techniques need to be developed to excise or cancel radio interference from the radio-astronomy signal received by a telescope. Such radio interference mitigation techniques are in their infancy, but will become increasingly important as the next-generation radio telescope, the Square Kilometer Array (SKA), is developed.

Radio Interferometer

A device that utilizes interference effects between radio waves in order to obtain higher angular resolutions than those achievable with individual radio telescopes.

The simplest form of radio interferometer consists of two antennae or dishes that point in the same direction but are separated by a distance (the 'baseline') that is large compared with the wavelength of the radiation that is being observed. Depending on the angle between the direction of the source and the direction of the baseline, wavefronts arriving at the two dishes from a given radio source may be in phase (a wavecrest arriving simultaneously at each dish) or out of phase. If the signals received by the two dishes are combined, they will interfere with each other. In particular, if they are exactly in phase, the two waves will add together to produce a signal of greater amplitude (constructive interference), whereas if they are 180° out of phase (a 'trough' arriving at one dish when a 'crest' arrives at the other), they will cancel to produce a signal of zero amplitude (destructive interference). Constructive interference occurs whenever the angle (θ) between the direction of the source and the normal to the baseline is such that the extra distance (d) traveled by a wavefront between arriving at one dish and the next is equal to a whole number of wavelengths. The condition for constructive interference is given by $\sin\theta = n\lambda/D$ where n is an integer, D is the separation between the dishes and λ is the wavelength of the radiation.

As a point source moves across the sky, and its direction relative to the baseline changes, the signals will shift in and out of phase with each other, so producing an interference pattern. Two neighboring point sources will produce overlapping interference patterns. Analysis of the interference pattern produced by the system enables the position of a point source to be determined and neighboring point sources to be resolved. Since an extended source can be considered to consist of a set of point sources, an interferometer can be used to resolve an extended source in detail. However, this resolution is achieved only along a direction parallel to the baseline. The resolving power of a two-element radio interferometer of this kind is given by $\lambda/2D$ (in radians), or $1.03 \times 105\lambda/D$ (in arcsec). Thus, for example, an interferometer consisting of two dishes separated by 1000 m and operating at a wavelength of 21 cm (0.21 m) would have a resolution of $0.21 \times 1.03 \times 105/103 \approx 20$ arcsec.

In more sophisticated interferometers, the separations between the dishes can be varied and more than two dishes may be included. Very-long baseline interferometry (VLBI) utilizes radio dishes separated by very large distances. The baselines in such systems can be thousands of kilometers long and, in principle, can be almost as great as the diameter of the Earth. The signals received by the two (or more) dishes are stored along with precise timing information and combined at a later date to produce interference patterns and to achieve resolutions that can approach 0.001 arcsec at centimeter wavelengths and 100 arcsec at millimeter wavelengths. VLBI using space-based instruments will improve resolutions even further.

Radio Sources

Extragalactic radio sources can be divided into two groups. One group consists of the star-forming galaxies—most optically bright galaxies, including STARBURST GALAXIES—which produce radio emission at a fairly low rate, about 10^{37} to 10^{40} erg s^{-1}. The radio emission from these is associated with by-products of stellar activity, such as particle acceleration caused by SUPERNOVAE, and is limited in extent to the size of the star-forming regions in the optical host galaxy. The second, much more powerful, group includes RADIO GALAXIES, radio-loud QUASARS, SEYFERT GALAXIES, and other normal galaxies with active nuclei. These galaxies, often collectively referred to as AGNs (ACTIVE GALACTIC NUCLEI), vary by a factor of more than 10^6 in their emitted power, reaching up to 10^{45} erg s^{-1} in the radio. In both star-forming galaxies and AGNs the radio emission is non-thermal and is almost certainly synchrotron emission from relativistic electrons moving in a magnetic field. How these various groups of galaxies are related, and what causes the huge variation in their levels of activity, remain major questions for astronomy.

Observations of H I in the COMA CLUSTER in the early 1980s revealed that for many normal (star-forming) galaxies there is a strong correlation between their radio continuum (RC) emission and far infrared emission (FIR). Since the radio emission is related to high-energy particles and magnetic fields, while the FIR is produced by warm dust, the physical basis for this correlation is not direct, and the tightness of the correlation is surprising: it has not yet been fully explained. Young massive stars appear to play an important role, presumably as a common energy source. The relationship is quite tight, holds for over five orders of magnitude in luminosity, and covers sources as diverse as blue compact DWARF GALAXIES, normal star-forming galaxies, Seyferts and radio-quiet quasars. Since the K-correction is quite different for the FIR emission from the dust (varying as λ^{-3}) and the radio continuum (varying as $\lambda^{0.8}$), this correlation makes it possible to get distances of starburst galaxies in the absence of optical REDSHIFTS.

Radio galaxies and radio-loud quasars have much more powerful radio emmisions, and a FIR-to-RC ratio that is about two orders of magnitude lower than that for normal star-forming galaxies, and with much greater scatter.

From the radio data alone, radio galaxies and quasars are indistinguishable. Both have extremely compact cores (nuclei) less than 1 pc in extent. Quasars differ from radio galaxies only by the extremely bright optical emission from their nuclei. In most cases this 'quasi-stellar' light makes it difficult to detect the fainter emission from the host galaxy, although such detections have now been made for many quasars using the Hubble Space Telescope. In both radio galaxies and quasars, thin jets emerge from the compact core and feed into diffuse radio lobes.

The first radio galaxy to be discovered, CYGNUS A, has just this classic form. This object, the strongest extragalactic radio source, appears in one of the earliest radio surveys, GROTE REBER's 1944 map. It was found again in subsequent surveys in 1948 and the source was double-lobed and more than a minute of arc in size: clearly, unusual astrophysics was at work here. The object was optically identified in 1954. Other radio sources—Centaurus A (NGC 5128), Virgo A (M87) and Fornax A (NGC1316)—had been identified with galaxies using the Dover Heights interferometer, and so it was clear that they were extragalactic. Cygnus A was found to be distant ($z = 0.06$), but still so intense that it would be in the 3C catalogue even if it were 20 times further away, and readily detectable anywhere in the universe. Hence, radio galaxies offered the first possibility of observing well beyond $z = 1$. At this time, the most distant objects known were at $z \ll 0.2$.

Early counts of these radio sources showed that they had to be a strongly evolving population: this effectively ruled out the then popular Steady State cosmology and provided early evidence for an evolving 'history' universe. But ironically, because of this strong evolution, radio galaxies did not turn out to be the powerful new tool for cosmology that astronomers hoped for. Until very recently, all radio source surveys have been dominated by a shell of sources at very great distance, picking up very few sources in the local universe, because the effects of cosmic evolution have totally outweighed those of geometry: more distant, and hence younger, sources have power great enough to completely offset the effects of the inverse-square law. Only the most recent surveys, those with enough sensitivity to detect sources below 1 mJy, have been able to detect fainter radio sources where the population starts to be dominated by the normal star-forming galaxies. These can be observed in large numbers at all distances, and so the study of distant radio sources has returned to the mainstream of extragalactic astronomy.

Fifty years after extragalactic radio sources were discovered we are still seeking to understand their details, but we do have a broad understanding of their energetics and evolution. After radio galaxies were discovered, the first questions that arose were: 'What supplies their energy?', 'Why are they double-lobed?' and 'What was it that made some galaxies active?' Some of these questions have been answered: we now understand that the energy supply is gravitational, and have coarse models to explain the double-lobed structure. But today we still need to understand: which galaxies have 'central engines'; the detailed relationship between the various classes of active galaxies and quasars; issues related to the speed, structure, collimation and symmetry of jets; which came first, AGNs or the black holes they are thought to house?; and how radio galaxies interact with their environment.

Radio Telescope

An instrument used to collect and measure radio waves from cosmic sources. In essence, a radio telescope consists of a collector of radiation, a detector, an amplifier (to enhance the weak cosmic signals) and a device to store, monitor and display the output from the system. Although the most familiar type of radio telescopes uses a concave dish to collect radiation, radio telescopes may take other forms, for example arrays of aerials or antennae arranged in rows or grids.

The archetypal collector is a parabolic dish that, like the primary mirror of an optical telescope, reflects incoming radiation to a focus. Radio waves arriving at the focal plane set up an electrical disturbance in an aerial, or antenna, that is fed to a receiver, tuned to the frequency of interest, which amplifies the weak incoming signal by factors of up to around 10^{15}. The output from the receiver may then be displayed directly by an output device, such as a chart recorder, or stored and processed in digital form by a computer. An image of an extended radio source may be produced by scanning the dish to and fro to record the intensity of the signal originating at different points on the source, storing the data and then constructing a map in which intensity values are plotted as contour lines or are color-coded to make up a false-color image.

Most dishes are steerable, and can be pointed to any location on the sky, but some are fixed. The largest steerable dish is the 100 m instrument at Effelsberg, near Bonn, Germany. The largest fixed dish is the 300 m (1000 foot) instrument that is built into a natural hollow at Arecibo, Puerto Rico.

As with an optical reflector, the resolving power of a radio dish is given by $1.22\lambda/D$, where λ is the wavelength of the radiation and D the aperture of the instrument. Because the wavelengths studied by radio telescopes are orders of magnitudes longer than optical wavelengths, the resolving power of a radio telescope is orders of magnitude poorer than that of an optical telescope of the same aperture. For example, the resolving power of a radio dish of aperture 100 m, operating at a wavelength of 0.5 m (about one million times longer than visible wavelengths) would be about 20 arcminutes (a third of a degree), much poorer than that of the human eye. The theoretical resolution of a 1 m aperture optical telescope is about 0.1 arcsec. In order to achieve this resolution, a radio telescope operating at a wavelength of 0.5 m would require an aperture of 1000 km; even at the shorter wavelength of 1 cm, an aperture of 20 km would be required. Clearly, this cannot be achieved with a single dish. Much improved resolutions can, however, be achieved by radio interferometers and aperture synthesis systems, instruments that combine the signals received by pairs or sets of dishes.

Because the wavelengths of radio waves are so much longer than those of visible light, radio dishes do not require to be shaped with the same degree of precision as the surfaces of optical mirrors. For example, irregularities in the reflecting surface of a centimeter, correspond to deviations of less than one-twentieth of the wavelength (a good level of precision for a reflecting surface) for an instrument that is studying emissions by clouds of hydrogen at a wavelength of 21 cm. At shorter wavelengths (centimeter or millimeter waves), the tolerances are proportionately finer. At longer radio wavelengths (above, say, 20 cm), a wire mesh surface rather than a solid metal skin can achieve good reflection. This lightens the dish considerably, and reduced the effect of the wind.

Radio Telescope Data Path for Single Dish and Interferometers

Radioastronomers derive all their observational data from the ELECTROMAGNETIC RADIATION which arrives at the RADIO TELESCOPE from the region of interest. The subset of parameter space of interest to the astronomer is modest: what part of the spectrum; what polarization; which direction; when and where the observations are made. The telescope is the filter which determines the actual subset, and care is required in order to ensure that the filter's characteristics are well understood.

This overview outlines the path from the raw data to the end product in the astronomer's hands.

The data

The radiation to be studied is generated by random natural processes, which leads to an incoherent mix of frequencies, in the form of Gaussian noise with statistical properties which are stationary on time scales which are usefully long—minutes to hours.

The incident wavefront can be described in terms of its *flux density* (power/unit area/unit frequency interval)[1]; Stokes parameters provide a convenient framework for describing the polarization characteristics. We also need to account for the directional properties if the radiation is from an extended region of space.

Single dish

This section examines the data flow in a single radio telescope, whether operating in a stand-alone mode ('single dish') or as an element of an array.

Figure 1 locates the major components of the data path.

The telescope optics

At the top of the chain we impose an angular distribution filter.

1. The reflecting surfaces. We want the telescope to be as sensitive as possible to the radiation from the target. To that end we build a structure with as large a collecting area as possible. In general the design is based on a paraboloid with a prime focus or with a secondary cassegrain or gregorian subreflector.

2. The feed antenna. In every telescope there is the problem of converting the energy in the focal plane to a useful form. Optical telescopes are able to exploit simultaneously a sizeable region of the focal plane, with the silver grains of a photographic emulsion or the active elements of a CCD array. Most radio telescopes are single-pixel devices, with just one active element in the focal plane. The interface device is the *feed antenna*, able to convert the converging ('focused') wavefront to an electrical signal suitable for the downstream electronics.

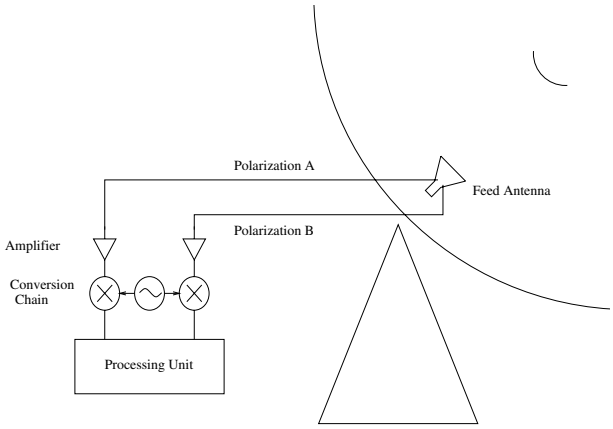

Figure 1. A generic radio telescope, identifying the main components in the data path.

The feed antenna needs to be tailored to the telescope optics to optimize the efficiency. In electrical terms this is a *matching* problem. The feed antenna is optimized for a particular electrical field over its aperture; therefore the telescope focussing must endeavour to produce that optimal field if the combination is to reach its peak efficiency.

3. The radiation pattern. There are several related ways to characterize the antenna's performance: effective aperture, efficiency, radiation pattern.

A wavefront from a distant target can be described in terms of its *flux density S*. An antenna with its optical axis normal to this wavefront will produce a signal of power density P (W Hz^{-1}) at the terminals of the feed antenna. The ratio P/S is called the effective aperture, and is related to the physical aperture by the efficiency:

$$A_{\text{eff}} = \eta A_{\text{physical}}.$$

The telescope does respond at some level to all wavefront directions; this is often expressed in terms of the peak effective aperture and the *radiation pattern*, $G(\theta)$, the effective aperture function normalized to the peak value.

In the general case of a telescope observing an extended source distribution the output at the feed antenna's terminals will be a convolution of the source distribution of wavefronts and the radiation pattern:

$$T(\theta_0) = \int T_{\text{source}}(\theta) G(\theta - \theta_0)\, \mathrm{d}(\theta).$$

$G(\theta)$ is a slow function of frequency—modern antennas, for example, often take the form

$$G(\theta) = 2\frac{J_1(U)}{U}$$

where J_1 is the first-order Bessel function, $U = 2\pi R \sin(\theta)$ and R is the aperture radius in wavelengths.

[1] The radioastronomer's unit of flux density is the Jansky (after the father of RADIO ASTRONOMY), and is : 1 Jy $= 10^{-26}$ W m^{-2} Hz^{-1}.

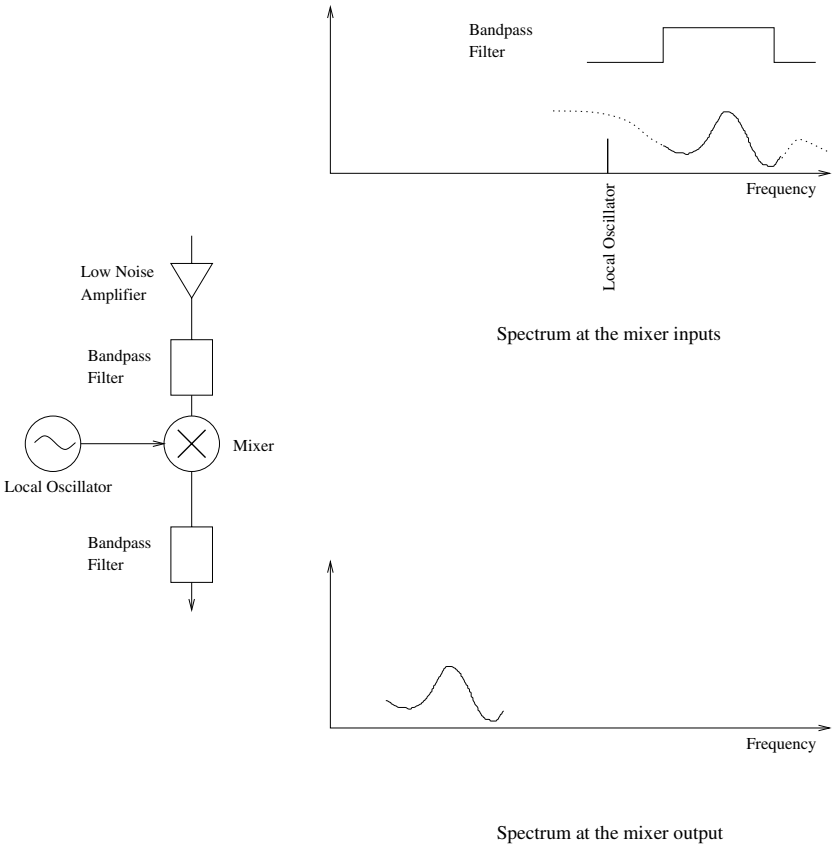

Figure 2. A generic mixing stage.

The polarization splitter

The polarization filter is the next stage—generally a device built into the feed antenna. The incoming wavefront is now transformed to two electrical waveforms, $V_A(f,t)$ and $V_B(f,t)$. The standard alternatives are orthogonal linear or circular polarizations. The critical point to note is that polarization information is encoded in the cross-correlations:

$$V_{AB}(t) = \langle V_A . V_B \rangle = \frac{1}{T} \int_{t-T/2}^{t+T/2} V_A(t).V_B(t)\,\mathrm{d}t.$$

Since the cross-correlations are only computed at the end of the conversion chain, it is important to ensure that the two waveforms are treated in identical ways, and that the relative phasing is carefully controlled. This has implications for the local oscillator machinery.

The discussion in the sections below will describe the treatment of a single electrical signal as it progresses down the conversion chain. A polarization-sensitive system will have two such chains, constructed to be as similar as possible.

The low noise amplifier

The signal at the output of the feed antenna is weak; it would be $P = 5 \times 10^{-24}$ W Hz^{-1} for a 1 Jy source observed by a 100% efficient 25 m diameter antenna; this is equal to the signal from a matched resistor at a temperature of 0.35K.

This poses a serious problem for the signal processing machinery which needs to detect this signal in the face of competing sources of noise.

The first line of defense is to provide amplification immediately after the feed antenna. Modern telescopes use low-noise amplifiers, with cooled electronics (10 K units are now in widespread use). The total noise competing against the signal will be somewhat higher than the raw temperature of the amplifier, as there will be contributions from lossy elements ahead of the amplifier, as well as contributions from the atmosphere, the universal cosmic mirowave background and the ground pick-up from the antenna's environment.

In a well designed system the signal-to-noise characteristics are established at this stage. The astronomical signal can be described in terms of T_A, the antenna temperature; this is the temperature of a hypothetical matched resistor which if placed at the terminals of the receiver would produce the same power (within the specified frequency range) as does the astronomical source.

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

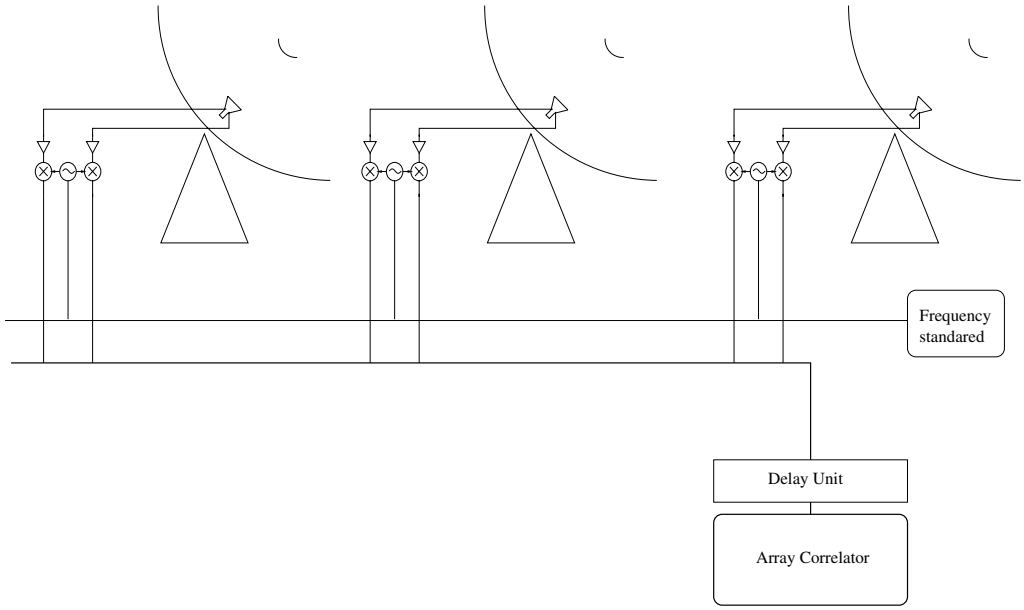

Figure 3. A generic interferometer array.

Competing against T_A is the system temperature ($T_{\rm sys}$) which describes in a similar way the noise generated by the system.

Modern systems operating in the centimeter wavelength band now achieve $T_{\rm sys}$ in the 20–50 K range.

The conversion chain

The feed antenna and the low-noise amplifier operate at the astronomer's chosen sky frequency, while the final stages of the signal processing operate at standard, low frequencies. This means that some form of frequency translation will be required; the conversion chain will isolate a section of the spectrum, a band of width B centered on $f_{\rm sky}$, and translate it to a band B centered on $f_{\rm base}$. In the process it must avoid introducing aliased artifacts. We need also to take care that the spectrum is not distorted.

The process, termed *mixing*, amounts to multiplying the input data stream by a reference signal from a *local oscillator* (LO). A generic mixing stage is shown in figure 2.

The mixing process is best understood in terms of a *Fourier series* description of the data. Given a stretch of data, T seconds long, then the voltage can be rephrased as

$$v(t) = \sum C_n \cos(2\pi f_n t + \phi_n).$$

The coefficient C_n is an estimate of the spectral power density at frequency f_n; the phase terms ϕ_n are uniformly distributed over the interval 0 to 2π.

The mixer performs the operation

$$v_{\rm mix}(t) = v(t)\cos(2\pi f_{\rm lo} t).$$

There will be a sum and a difference product for every frequency component in the input signal. Two filtering operations are therefore required: on the input side we need to ensure that all the frequencies are on just one side of $f_{\rm lo}$ if we wish to avoid a folding of the spectrum; and on the output side we need to separate the 'sum' components from the 'difference' components.

A single LO, split between the two polarization signals will ensure that the polarization properties (the cross-correlations) are not compromised.

The processing unit

A sampler (an analog-to-digital device) is almost inevitable as it is probable that the data will be processed by a computer. The sampler must operate at least at the Nyquist rate, $2B$, where B is the bandwidth of the signal if spectral information is not to be lost.

A CORRELATOR is increasingly the workhorse at this point in the chain:

- in the autocorrelator mode it will produce the spectral distribution.
- the polarization (Stokes) parameters can be derived from the four correlation products of the two polarization signals ($C_{AA}, C_{AB}, C_{BA}, C_{BB}$).

Interferometer array

The INTERFEROMETER array is the radioastronomer's imaging device.

Figure 3 shows the additional components needed to combine a number of radio telescopes into an array.

The subunits of the array are single dish telescopes. The array operation requires the telescopes to operate coherently; the hardware modifications to achieve this are:

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

(a) The conversion chains must be phase coherent; this can be achieved by driving all the local oscillators from a common frequency standard[2].
(b) All the data streams are returned to a common processing unit, the array correlator.
(c) The imaging algorithms require the data to be transformed to the coordinate frame which has its z-axis oriented towards the center of the field of interest. Let $\hat{\varepsilon}$ be the unit vector towards the field center, and $\vec{r}_{AB}$ be the baseline vector for the antenna pair (A,B); then the data from antenna (A) will need to be delayed by an amount $\tau = (\hat{\varepsilon} \cdot \vec{r}_{AB})/c$ in order that the data streams remain aligned on common wavefronts. Since $(\hat{\varepsilon} \cdot \vec{r}_{AB})/c$ changes with time (as the Earth rotates) τ will need to be adjusted continuously.

An additional (dynamic) phase correction must be made at the local oscillator if, as is usually the case, the delays are applied at baseband (at the end of the conversion chain).

A computer is obviously part of the data chain; this is particularly so when imaging with an interferometer array. Imaging is possible because the array exploits the Van Cittert–Zernicke theorem. It samples the complex coherence function of the extended target. A number of operations are required before the image is delivered to the astronomer:

(a) The data collected in time-order need to be sorted so that the 2D coherence function can be estimated.
(b) The coherence function is Fourier transformed to the image domain.
(c) Calibration and data quality checks will be needed.
(d) The coherence function is rarely fully sampled—the location of the sampling is set by the antenna locations; this means that the raw image contains signatures ('artefacts') reflecting the sampling function. Procedures, some based on *maximum entropy* algorithms, are available to account for these signatures and provide a usable image.

Radioactivity

The spontaneous decay of certain unstable atomic nuclei through the emission of alpha particles (helium nuclei), beta particles (electrons) or gamma radiation. This process, otherwise known as radioactive decay, changes ('transmutes') the original ('parent') atomic nucleus into a ('daughter') nucleus of another element. If the resulting nucleus is itself unstable, further radioactive decay will ensue until, after a series of stages, the original nucleus has been transmuted into a stable nucleus and radioactivity ceases.

For a nucleus of element X, with atomic number Z (equal to the number of protons in the nucleus) and mass number A (equal to the total number of protons and neutrons in the nucleus), which is denoted by ${}^{A}_{Z}\mathrm{X}$, alpha emission (the emission of a helium nucleus, ${}^{4}_{2}\mathrm{He}$, which contains two protons and two neutrons) reduces A by 4 and Z by 2. Beta emission, the most common form of radioactivity, usually results from the spontaneous decay, within the nucleus, of one of its constituent neutrons into a proton, an electron and an antineutrino. This process (beta decay) increases the atomic number by 1 but leaves the mass number unchanged (the number of protons increases by one and the number of neutrons decreases by one) and is accompanied by the emission of an electron and an antineutrino. With either type of decay, if the resulting nucleus is formed in an excited state it will 'de-excite' (drop to a lower energy level) by emitting gamma radiation.

The time taken for half the nuclei in a sample of radioactive material to decay is known as its half-life, each radioactive nuclide (nucleus of a particular isotope) having its own characteristic half-life. The half-lives of the various radioactive nuclides range from fractions of a microsecond to billions of years. For example, ${}^{238}_{92}\mathrm{U}$, by far the most abundant of the 14 different isotopes of the element uranium, undergoes alpha decay with a half-life of 4.5 billion years. The decay process continues via a series of much faster decays, terminating eventually in the production of the stable isotope of lead, ${}^{206}_{82}\mathrm{Pb}$. Radioactive decay can be used to estimate the time that has elapsed since a sample of material (e.g. rock) has solidified. For example, if a sample of lead, formed by the radioactive decay of uranium, is analyzed, and the relative proportions of the remaining quantity of the parent uranium and daughter lead compared, then, knowing the half-life of uranium, the age of the sample can be calculated. The ages of the Earth, of meteorites and of samples of lunar rock have been calculated by this technique. Younger materials can be dated by means of shorter-lived radioactive isotopes such as carbon-14 (${}^{14}_{6}\mathrm{C}$), which decays through beta emission with a half-life of 5570 years.

Radioastron (Spectrum-R)

Russian–US radio astronomy satellite which may launch in 2000–2001. Designed as part of a very long baseline interferometry programme which involves linking the satellite with ground receivers. The satellite carries a 10 metre antenna and will observe from a highly elliptical orbit of $4000 \times 77\,000$ km. Intended to study compact radio sources such as quasars and galactic nuclei at extremely high resolution (3×10^{-5} arcseconds).

Radioastronomical Institute, Ukraine

Located in Chervonopraporna near Kharkov. The institute aims its research efforts at: developing the theory and design principles of radio telescopes; ground-based radioastronomical observations at decimeter and millimeter wavelengths; investigations of the Earth and other planets, terrestrial environment and interplanetary space by radioastronomy methods.

For further information see http://www.nas.gov.ua/d/d4/nas_d4i9.html.

Radioastronomy

Mankind has been fascinated by what one can see in the heavens for thousands of years. The human eye is sensitive to a narrow band of the electromagnetic spectrum from about 4000 to 6600 Å wavelength. Astronomical objects, however, emit electromagnetic radiation across most of the spectrum from meter wavelengths in the radio band to sub-angstrom wavelengths in the x-ray/gamma-ray bands. This article concerns itself with the radio band, which traditionally covered meter and centimeter wavelengths, but more recently has expanded to shorter wavelengths as radio instrumentation has been developed for millimeter and sub-millimeter wavelengths.

If one were to have eyes sensitive only to radio waves, the Sun, the planets, and the Milky Way would be recognizable, yet different. The Sun would still be extraordinarily bright. However, the tenuous and extremely hot plasma comprising the solar corona would cast a diffuse, luminous haze around the Sun. The planets would shine on their own, instead of in reflected light from the Sun. The Milky Way, the spiral galaxy in which we live, would still glow. However, the radio light would not come from stars too numerous to discern, but instead it would come from highly energized electrons.

The radio sky would also have many new and fascinating features. Few stars could be seen, and these would be double stars so tightly bound together that they interact strongly gravitationally and magnetically. Old stars which have undergone massive explosions, called supernovae, would form large shell-like 'lanterns' which decay in strength slowly over human lifetimes. As these lanterns dimmed, one would occasionally find a remnant beacon or pulsar providing regular pulsating radio waves. The radio sky would also be littered with numerous dumbbell-shaped structures associated with distant galaxies, some near the 'edge' of the universe. Finally, the sky would not be totally dark, as the remnant light from the Big Bang explosion that created the universe continues to bathe us in faint radio waves.

Early history

KARL JANSKY made the first radioastronomy observations in the early 1930s. Jansky was working for the Bell Telephone Laboratories, investigating the sources of interference which might affect transatlantic phone calls. He built a rotatable antenna sensitive to emissions at a wavelength of 15 m and found sources of 'static' coming from local thunderstorms, distant thunderstorms in the tropics and an unknown steady source. The peak of the steady source drifted in position at the same rate at which stars drift across the sky from night to night (about 4 min per day), indicating an extraterrestrial origin for the emissions. Jansky had discovered synchrotron emission associated with energetic electrons accelerated in the magnetic field of the Milky Way.

The astronomical community did not fully appreciate the significance of Jansky's discovery for decades. One of the few who followed up on Jansky's results was GROTE REBER. Reber built a 9 m diameter parabolic reflector to investigate the strength of the radio emission from the Milky Way at meter and centimeter wavelengths. His antenna–receiver system was not sensitive enough to detect the Milky Way at centimeter wavelengths, but he did detect and map the Milky Way at 1.9 m wavelength.

Both Jansky and Reber detected broad-band radiation, analogous to the continuous static in radio reception found between man-made radio channels. Dutch astronomers sought a spectral feature, radiation at a particular frequency analogous to the narrow-band emission from a radio station. Spectral features, or lines, in the radio band come from atoms or molecules, similar to those seen optically. With a spectral line, one can measure a frequency (or Doppler) shift indicative of the relative motion between the source and the observer. A transition of atomic hydrogen at a wavelength of 21 cm provided a candidate, and some years later this line was detected at Harvard University. Observations of atomic hydrogen have been used to study the structure of the Milky Way as well as to measure the mass of other galaxies. A major advantage of observations at radio waves, compared with visible light, is that one can see through interstellar dust grains which hide most of the Milky Way from view at optical wavelengths.

Radioastronomy grew rapidly following the Second World War, aided by the significant wartime investment in radio equipment for use in radar systems. The Sun was shown to be a strong radio source, along with some other isolated sources. The strongest source in the constellation of Taurus, called Taurus A, was identified with the Crab Nebula, a remnant of the AD 1054 supernova chronicled by Chinese astronomers. Another isolated radio source, Cygnus A, proved difficult to identify. Ultimately it was associated with a distant galaxy with a peculiar optical morphology, and Cygnus A became the archetypal member of the important class of objects called radio galaxies.

Radio telescopes

Radioastronomy developed rapidly and some very large telescopes were built. A 250 ft (76 m) diameter, fully steerable telescope was built in England in the 1950s, and other large telescopes were built in Australia, the United States and elsewhere. In the early 1970s, the Effelsberg 100 m telescope (see figure 1) in Germany, the world's largest fully steerable radio telescope, came into operation. The largest (partially steerable) telescope is the Arecibo 1000 ft (305 m) telescope in Puerto Rico. This telescope has a fixed spherical primary reflector, built over a large natural depression, and complex movable radio 'optics' suspended near the primary focus.

The diffraction-limited resolution of a telescope is approximately λ/D, where λ is the observing wavelength and D is the telescope diameter. For the ARECIBO OBSERVATORY operating at 6 cm wavelength, this corresponds to a resolution of about 40 arcseconds, comparable to that of the human eye, but far poorer

than the ≈1 arcsecond (atmospherically limited) resolution achievable by telescopes at optical wavelengths. The construction of a centimeter wavelength radio telescope with ≈1 arcsecond resolution would require a diameter of ≈10 kilometers, which is not technologically feasible. However, arcsecond and better resolution has been achieved though radio interferometry as discussed below.

Imaging in radioastronomy

Single telescopes

Photography produces an image which typically contains millions of picture elements, or pixels. This is achieved with photographic film (or plates) placed in the focal plane of a camera (or telescope). There is no analogous photographic film for radio waves, and radio astronomers have been able to place only a small number of detectors in the focal plane. Thus, maps of radio sources have been generated laboriously by moving the telescope across the source and recording its intensity pixel by pixel. Ultimately, an 'image' of a radio source can be displayed on a computer monitor. While single radio telescopes can image an arbitrarily large field of view, the finest angular resolution, or smallest useful pixel size, is limited by the diameter of the telescope.

Interferometry

The appetite for radio images with angular resolution finer than can be reasonably obtained with single telescopes was satisfied in an elegant manner with RADIO INTERFEROMETERS. Unlike optical interferometry, for which direct combination of light from different telescopes (or segments of one telescope) is employed, a radio interferometer makes use of coherent amplifiers that preserve both the amplitude and phase of the incoming electromagnetic waves. The signals from the individual telescopes can then be replicated without significant loss, distributed and combined with signals from other telescopes.

Combining signals coherently from two telescopes is analogous to what occurs when light from a laser propagates through two pin holes to yield a sinusoidal interference pattern on a screen. One can think of two radio telescopes as pin holes to view the sky and then understand that a radio interferometer is responsive to the sky brightness modulated by a sinusoidal interference pattern. If a mathematical function is multiplied by a sinusoid and then summed (integrated), one obtains a Fourier coefficient of the function. Thus, radio interferometers provide Fourier coefficients of the sky brightness.

One can accumulate many Fourier coefficients of the sky brightness by combining signals from many pairs of telescopes and also by taking advantage of different projections of telescope separations (as seen from the source) provided by the Earth's rotation. These Fourier coefficients can be placed on a grid, called the (u, v)-plane, whose axes are the eastward and northward projection of the antenna separations, and a two-dimensional inverse Fourier transform performed to recover an image of the sky. The result is that each telescope acts as a piece of a giant telescope, equal in size to the maximum separation of individual telescopes. One achieves the angular resolution, but not the light collecting capacity, of the giant telescope. This technique, called aperture or Earth-rotation synthesis, was pioneered by MARTIN RYLE in England who received a Nobel Prize for this work in 1974.

Large-scale interferometers involving many individual telescopes have been built in the Netherlands (Westerbork) and in the United States (the VERY LARGE ARRAY NRAO; see figure 2) and have achieved angular resolutions of better than 0.1 arcseconds. In the mid 1960s some sources of radio emission (radio galaxies and molecular masers) were found to contain structures much smaller than could be resolved with existing interferometers. This motivated radioastronomers to seek even higher resolution by combining signals interferometrically from telescopes across the Earth. This was achieved by tape recording the voltages received at each telescope with a precise timing signal available from atomic clocks. The tapes were then shipped to a 'correlation' facility where the data streams from pairs of telescopes were played back, carefully aligned in time, and cross-multiplied. This technique, called Very Long Baseline Interferometry (VLBI), achieved the astounding angular resolution of ≈0.001 arcseconds and revealed remarkable properties of bright sources. Recently, VLBI techniques have been extended to link a radio telescope in space (the Japanese 'Halca' spacecraft with the 8 m 'VSOP' telescope)

with arrays of ground telescopes, yielding interferometer baselines of about three times the Earth's diameter.

Millimeter wavelengths

In recent decades much of the emphasis in radioastronomy has been on observations at shorter wavelengths. The pioneering work of millimeter wave telescopes, such as the Bell Labs 7 m, the Texas 5 m, the NRAO 12 m (originally 36 ft), the FCRAO 14 m and the Onsala 20 m, opened up the field of observational molecular spectroscopy. Carbon monoxide (CO) was detected in 1970 from giant molecular clouds, whose dense cores have now been studied in line emission from many other molecules. Molecular line observations have enabled astronomers to study the star formation process in these clouds in great detail. Following up on these breakthroughs, two large millimeter wave telescopes were constructed in the 1980s: the NOBEYAMA RADIO OBSERVATORY 45 m in Japan and the INSTITUTE DE RADIOASTRONOMIE MILLIMETRIQUE (IRAM) 30 m in Spain. These telescopes, which operate at wavelengths as short as 1 millimeter, have greatly added to our understanding of the distribution of molecular clouds in the Milky Way and the chemical processes which operate in these clouds.

Interferometry techniques have been developed to work at millimeter wavelengths at the Berkeley–Illinois–Maryland (originally HAT CREEK RADIO OBSERVATORY) and the OWENS VALLEY RADIO OBSERVATORY arrays in California, the Nobeyama array in Japan, and the IRAM array in France. The high angular resolution afforded by these interferometers has allowed astronomers to study disks surrounding newly formed stars, elucidate the nature of spiral arms in galaxies, and detect emission from molecular gas and dust at cosmological distances.

Electronics

Radioastronomy has benefited immeasurably from the development of low-noise amplifiers. The added noise can be exceedingly small, equivalent to a black-body radiator whose temperature is only a few degrees above absolute zero. Today the preferred amplifier is a cooled HFET (heterostructure field-effect transistor) device. These devices work best at centimeter wavelengths. For shorter wavelengths it is advantageous first to shift, or mix, the observing band to a longer wavelength where HFET amplifiers can be used. Currently this is accomplished with an electronic device made up of a triple-decker 'sandwich' comprising a superconducting layer, an insulating layer and another superconducting layer (SIS), which provides the mixing with little added noise.

Digital electronics have also had a dramatic effect on radioastronomy. In 1961, Sander Weinreb constructed the first digital spectrometer for radioastronomy. This instrument digitized the amplified voltage from a telescope and formed the autocorrelation function by multiplying replicas of the voltage delayed in time by different amounts. The autocorrelation function was then Fourier transformed to yield the source spectrum. In early CORRELATORS, digitization involved clipping, or 1-bit sampling, a process by which positive voltage is conceptually represented by a +1 and negative voltage by a −1. Although one would suspect that retaining only the sign of the voltage would lose most of the information in the signal, a mathematical relationship (derived by J H Van Vleck during the Second World War) demonstrates that one retains the essential character of the spectrum, losing only a factor of $2/\pi$ in signal-to-noise ratio. Often this loss of signal-to-noise ratio is offset by the exceptional stability of digital correlation, allowing one to integrate noise levels down for long periods of time without encountering systematic effects, such as frequency-dependent gain variations, that plague analog spectrometers.

In addition to spectrometers, digital correlators are used to cross-multiply signals from pairs of telescopes used as an interferometer. These correlators are special purpose digital computers which perform an astounding number of operations per second. For example, the Very Large Array correlator, which was built in the early 1980s, processes data from each telescope coming in at hundreds of megasamples per second. It cross-multiplies these signals for all 351 independent pairings of the 27 individual telescopes, corresponding to an aggregate processing speed of over 100 000 megahertz!

Discoveries in radioastronomy

Radio galaxies

The discovery of radio galaxies is one of the many achievements of radioastronomy. At first, the origin of these sources was uncertain. The radio emission was resolved with interferometers and presented as two giant 'lobes' as shown in figure 3. Once accurate positions for the radio emission from these sources were obtained, astronomers noted that they were often centered on distant, giant galaxies—usually the dominant galaxy at the center of a large cluster of galaxies. These lobes are among the largest structures in the universe—some separated by more than a million light years, or nearly a hundred times the size of our Milky Way. The radiation mechanism is

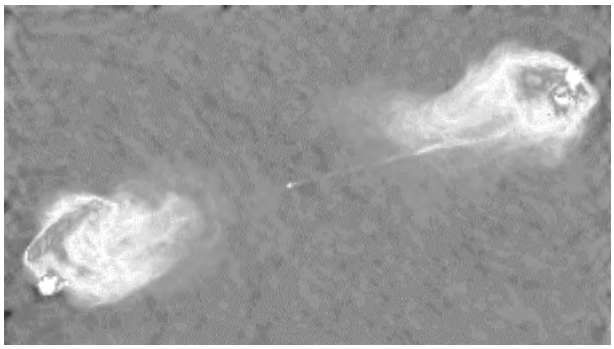

Figure 3. The radio galaxy Cygnus A as imaged by the VLA at a wavelength of 4 cm. Note the large double lobes of radio emission and the thin jets connecting the lobes to the nucleus of the galaxy at the center of the image.

now understood to be incoherent synchrotron emission, which comes from electrons excited to nearly the speed of light and then accelerated in a spiral motion around a magnetic field line. Remarkably the minimum possible energy contained in energetic particles and magnetic fields needed to power radio galaxies can exceed $10^7 M_\odot c^2$—that is the total conversion of the mass of 10 million Suns into energy!

What is the source of this phenomenal amount of energy in radio galaxies? The symmetrical placement of the lobes about a central galaxy clearly suggested a galactic link. Next, the discovery of thin jet-like structures connecting the lobes with the centers of the galaxy indicated a channel for the energy to flow. Finally, images of the nuclei of radio galaxies made with VLBI indicated that these JETS continued down to scales less than 0.001 arcseconds, or typically less than 1 parsec. Thus, a strong circumstantial case was made that the mass of far more than 10 million Suns must have flowed through a tiny region at the center of a radio galaxy, smaller than that from the Sun to its nearest neighboring star, and then was converted into energy! This reasoning lead to the current understanding that SUPERMASSIVE BLACK HOLES power radio galaxies.

Quasars and superluminal motion

Large portions of sky were observed at ≈1 m wavelength, such as by the third Cambridge (or 3C) survey, and astronomers sought optical identifications for the newly discovered sources. While many radio sources could be associated with supernova remnants in the Milky Way or with radio galaxies, one class of sources appeared as bluish, star-like objects called quasistellar radio sources or quasars. In 1963, astronomers at Caltech identified spectral lines in two quasars, the BRIGHT QUASAR 3C 273 and 3C 48, as having extraordinarily high recessional velocities (or 'redshifts'). Distances to these objects obtained from their redshifts using the Hubble law indicated extremely great, cosmological, distances and, correspondingly, extremely high intrinsic luminosities. The cosmological interpretation of high redshifts was controversial since quasars would then be the most luminous objects in the universe. (Recently, however, nearly all astronomers have come to accept this interpretation. Indeed, 'normal' galaxies have been found with red shifts greater than 4, making the 'extreme' redshift of 3C 48 of 0.4 unremarkable today.)

Quasars, along with radio galaxies and many other types of galaxies which exhibit strong nuclear activity, are all thought to be powered by accretion of matter onto supermassive black holes. Early VLBI observations of some quasars revealed an usual morphology: emission dominated by a small number of 'blobs' which appeared to expand at speeds exceeding that of light. This phenomenon, called SUPERLUMINAL MOTION, has been well studied for decades and numerous quasars have been found to exhibit superluminal motion. Apparent superluminal motion is explained quite simply in terms of the constant and finite speed of light (and radio waves). A source moving at nearly the speed of light and nearly along the line of sight toward an observer can almost keep up with its own light, causing the observer to see events in the source greatly speeded up.

The cosmic background

In 1965 ARNO PENZIAS and ROBERT WILSON, working at the Bell Telephone Laboratories, discovered that 'blank sky' is not totally dark at radio wavelengths. Instead, the universe is bathed in a 'cosmic background' (see COSMIC MICROWAVE BACKGROUND) of radiation, which has an intensity equivalent to that of emitting material (a black-body) at a temperature of 2.7 K (equivalent to about −270.4 °C). The cosmic background is the cooling remnant of the Big Bang 'explosion' that marked the origin of the universe. Recently, the Cosmic Background Explorer (COBE) satellite confirmed that the spectral shape of the emission corresponds precisely to what would be expected for a black-body. COBE also detected fluctuations in the background, which could possibly explain the formation of galaxies in the Universe.

Pulsars and supernova remnants

In the mid-1960s, ANTHONY HEWISH in England led the construction of a telescope capable of studying variable radio emissions. Some radio sources were known to be variable, owing to propagation effects (scintillation by free electrons) in the interstellar and interplanetary medium. In 1967, JOCELYN BELL observing with this telescope unexpectedly discovered sources of pulsed radio emission with very regular periods (∼1 s). Pulsars, as they are now called, are formed in explosions of evolving, massive stars. During the explosion the outer envelope of the star is expelled, while the inner portions are compressed so strongly that protons and electrons join to make neutrons. These 'neutron stars' typically contain about 40% more mass than the Sun and yet have a radius of only about 10 kilometers! The formation of a neutron star also leads to astounding magnetic field strengths (∼10^{12} G)

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

and to rapid rotation (∼1 Hz). We see intense radio emission when the magnetic pole sweeps by at the star's rotation rate, if the rotation axis and the magnetic pole are misaligned.

More recently, RUSSELL HULSE and JOSEPH TAYLOR discovered a double-star (binary) system containing a pulsar. Precise timing of the pulsar signals over many years has lead to the detection of changes in the orbit of this binary pulsar caused by energy loss owing to gravitational radiation as predicted by Einstein's theory of general relativity. Hulse and Taylor received the 1993 Nobel Prize for this discovery, joining Hewish who received this prize in 1974 for his role in discovering pulsars.

The supernova explosion also creates a shock wave which expands into the interstellar environment, plowing up and exciting a hot sphere or shell-like region. The hot electrons in such SUPERNOVA 'REMNANTS' are strong radio sources and can be seen throughout the Milky Way and in other galaxies.

The galactic center

The central region of our Milky Way has proven to be rich in a variety of phenomena, containing numerous supernova remnants, massive star-forming clouds, strong x-ray and gamma-ray sources, and towering magnetic structures which protrude from the galactic plane (see figure 4). In the early 1970s, an intense radio source was discovered in the galactic center. This radio source, called SAGITTARIUS A (Sgr A)*, is very compact, with an intrinsic size less than the distance from the Sun to the Earth (1 AU), and appears to mark the center of our rotating galaxy. Stars in a dense cluster surrounding Sgr A* move at speeds exceeding 1000 km s^{-1} at projected distances of 3000 AU from Sgr A*. These high speeds, if resulting from gravitationally bound orbits, indicate that Sgr A* contains about 3 million solar masses. While stars around Sgr A* move rapidly, Sgr A* itself appears stationary, suggesting that it is far more massive than the stars surrounding it. The evidence is very strong that Sgr A* is a supermassive black hole, a diminutive relative of the supermassive black holes that power quasars and radio galaxies.

Gravitational lensing

One of the predictions of Einstein's theory of general relativity is that gravitational mass bends light and therefore acts as a lens. Gravitational lenses magnify background sources, distort their appearance, and even create multiple images of a single source. In 1979, 0956+571, a source discovered in a large radio survey, was imaged and found to consist of two compact objects separated by only about 6 arcseconds. Subsequent optical observations revealed that the two objects were quasar-like and had nearly identical spectra. While it was conceivable that two quasars could form in the same environment and have similar properties, the possibility that these 'quasars' were two images of the same object was a simpler explanation. Recently, fluctuations in the two 'quasars' have been shown to be nearly identical, except for a time difference of roughly one year as expected if there is one quasar whose light reaches us along two different paths with different path lengths. This provides conclusive evidence of GRAVITATIONAL LENSING. In the past 20 years dozens of other lensed systems have been identified. In these systems, the lens is formed by the gravitational mass of a galaxy or a cluster of galaxies.

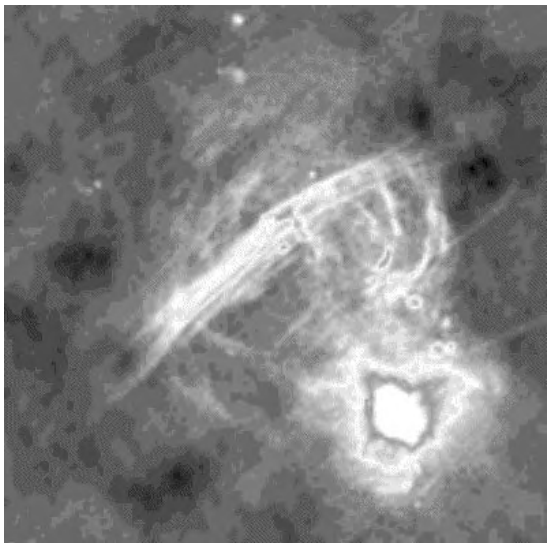

Figure 4. An image of the central region of the Milky Way made with the VLA at a wavelength of 4 cm. The filamentary structure near the center of the image indicates a complex network of magnetic field lines. The actual center of the Milky Way, probably a supermassive black hole containing a few million solar masses, is hidden in the center of the brightest region near the lower right corner of the image.

Molecular clouds

Life as we know it on Earth involves very complex chemical processes which give rise to many organic molecules. It had been thought that such molecular complexity could only evolve on planets. However, in the 1970s radioastronomers started to discover many molecules, including water, ammonia and simple organic molecules, in clouds of interstellar gas. At centimeter wavelengths detectable spectral lines are rare. However, at millimeter, and especially at submillimeter wavelengths, the spectrum is nearly completely covered with detectable lines of molecules, e.g. methyl alcohol (CH_3OH). Over 100 different molecular species have been identified; some species, such as $HC_{11}N$, contain more than a dozen atoms. These molecular clouds, as they are now called, are the sites of the formation of stars and planets and provide the building blocks for life.

Masers

One of the early surprises of molecular spectroscopy in the radio band was the discovery of extremely strong emission lines from the hydroxyl (OH) radical. These lines were not only thousands of times stronger than

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

expected, they also were extremely narrow and highly polarized. Originally dubbed 'mysterium' because of these remarkable properties, the emission was correctly understood as coming from a natural amplification process, called a maser, analogous to the process that results in (optical) lasers. Masers have been detected in many molecular species, such as water vapor and methyl alcohol. Water vapor displays the most spectacularly strong signals of any known maser species. In fact, a water maser in a star-forming region called W49, located most of the way across the Milky Way, puts out as much energy in one narrow spectral line as the Sun does across the entire visible band.

Sun and planets

As early as the 1940s, the Sun was found to be a very strong and complex source of radio emission. Intense, sporadic, low-frequency emissions were detected by radar equipment during the Second World War but these discoveries were kept classified until the end of the war. A variety of solar flares were seen and found to be associated with sun spots and other active regions.

Early radio observations of the planets also revealed diverse and fascinating characteristics. Optical astronomers thought they had established that Mercury's spin and orbital periods were equal (as occurs for our Moon owing to tidal effects). Thus, it was a great surprise when early radar observations revealed that MERCURY instead rotates three times for every two orbits about the Sun. In retrospect, the erroneous conclusion that Mercury's spin and orbit were locked was based on images which were obtained only when the planet was near the maximum elongation from the Sun; with such poor sampling many spin periods could fit the same data.

Early radio measurements of the brightness of VENUS indicated very high temperatures, and this was thought to indicate a hot ionosphere. However, the polarization of the radio emissions confirmed that the high temperature, about 750 K, came from the planet's surface. The high surface temperature of Venus is understood to be due to a strong 'greenhouse' effect, in which visible light from the Sun heats the planet, evaporates its oceans and produces an extremely dense atmosphere. Infrared emission cannot easily escape the atmosphere, preventing cooling, and further elevating the temperature.

JUPITER, surprisingly, was found to have strong emission at about 10 cm wavelength, which was shown to be synchrotron in nature. Even more surprising was the discovery of sporadic emission at about 10 m wavelength, which comes from electrical discharge involving the interaction of Jupiter's innermost satellite, Io, with the magnetic field of the giant planet.

Future directions

The current trend in developing major new telescopes for radioastronomy is toward interferometric arrays. Distributing the collecting area of an instrument among many individual telescopes can greatly reduce costs and at the same time increase angular resolution compared with building single large telescopes. Extremely ambitious projects are currently planned or being developed. For example, a millimeter/sub-millimeter wavelength array called the Atacama Large Millimeter Array (ALMA) will soon be built by an international collaboration involving the United States, Europe and possibly Japan. This array is planned to consist of more than 50 12 m diameter telescopes spread over an area of about 10 km on an exceptionally dry 5000 m elevation site in northern Chile.

Looking toward the future, radioastronomers in many countries are working to develop the technology necessary to build a centimeter wavelength telescope with a collecting area of one square kilometer! This would represent an increase in collecting area of about a factor of 70 over the VLA and a factor of about 15 over Arecibo.

The far future for radioastronomy will probably involve radio telescopes in space. The weightless environment of space should allow large, low-mass telescopes to be constructed, extremely long interferometer baselines and decreased exposure to man-made interference. The latter benefit of space may be the most important, as the explosion of electronic technologies has resulted in a dramatic increase in the pollution of the radio band from fixed and satellite transmitters broadcasting a variety of data from telephone calls to television programs.

Ramsden, Jesse (1735–1800)

Instrument-maker, born in Halifax, Yorkshire, England, the most outstanding maker of precision scientific instruments of the eighteenth century, producing extremely precise scaled circles. In 1775, he made the first dividing machine that could enscribe precise divisions on the borders of small-diameter circles. He made the theodolites with 3 foot diameter circles used in triangulation to connect the geodetic networks of France and England, and the large altazimuth instrument with a 5 foot diameter vertical circle built for PIAZZI. His telescopes used achromatic lenses according to DOLLOND's design (Ramsden was married to his younger sister). His name is commemorated in the design of the *Ramsden eyepiece*.

Ray

A bright linear feature on a planetary body formed by ejecta from a recent crater-forming impact. Surface material darkens with age through exposure to radiation, so rays, consisting of freshly excavated material, are bright by contrast. In addition, some impacts have sufficient force to vaporize surface material, which can resolidify in a reflective, glassy form. Rays extend from their associated crater, often in a radial pattern known as a *ray system*. The best-known ray systems are lunar, the most prominent being the one surrounding the crater Tycho, which is very prominent at full moon, individual rays extending for a thousand kilometers or more. Other solar system bodies with rays are Mercury and Ganymede.

Rayleigh Limit

The theoretical resolving power of a telescope according to a criterion devised by Lord Rayleigh (1842–1919). Because of the phenomenon of diffraction the image of a point source of light (such as a star) produced even by a perfect optical instrument consists of a central bright spot (the Airy disk) surrounded by concentric dark and light rings. If two point sources are very close together, the resulting image will consist of two overlapping diffraction patterns. According to Rayleigh's criterion, two close point sources of light may just be resolved if the angle between them is such that the center of the Airy disk corresponding to the image of one source falls on the first minimum in intensity in the diffraction pattern of the other (i.e. the first dark fringe around the Airy disk of the other source). Under these circumstances, assuming an ideal optical system, there will be a drop in light intensity of 20% mid-way between the centers of the two Airy disks.

The Rayleigh limit is given, in radians, by $\alpha = 1.22\lambda/D$, where λ denotes wavelength and D denotes the aperture of the telescope; and in seconds of arc by $\alpha = 2.52 \times 10^5 \lambda/D$. Thus, for example, the theoretical resolution of a telescope with an aperture of 0.1 m, for light of wavelength 550 nm (5.50×10^{-7} m), is $2.52 \times 10^5 \times (5.50 \times 10^{-7}/10^{-1}) \approx 1.4$ arcsec.

Reber, Grote (1911–2002)

American radio engineer, born in Chicago, IL. After reading JANSKY's articles on radioastronomy he built (1937) the world's first radio telescope (a 9 m tiltable paraboloid) in his backyard in Wheaton, IL. With it he detected radio emission ('cosmic static') at 1.9 m wavelength from the Milky Way. With an improved receiver in 1941 he detected the Sun and a strong source in Cassiopeia (Cas A). As a self-employed researcher in Hawaii and Tasmania he mapped the background radiation at 1–2 MHz. He produced the first radio maps of the sky.

Receivers: Millimeter and Longer-Wavelength Feeds and Receivers

The frequency range over which ground-based RADIO ASTRONOMY observations can be carried out extends from about 2 MHz ($\lambda = 150$ m) at the low-frequency end to near 1 THz ($\lambda = 350\ \mu$m) at the high end. This discussion treats systems and techniques from the low-frequency limit up to a frequency of 300 GHz ($\lambda = 1$ mm); submillimeter systems and techniques are dealt with in the next article (see also MILLIMETER AND SUBMILLIMETER ASTRONOMY).

Within this very broad range of frequencies, astronomers measure the properties of incoming cosmic radiation in the form of broadband continuum or narrowband spectral-line emission. This incoming radiation is collected by the RADIOTELESCOPE, amplified, detected and recorded by a sensitive radio receiver mounted on the telescope, and then processed in such a way as to display the output as a flux density measurement, or as a spectrum of the frequency band to which the receiver is tuned.

The power levels of the received signals are extremely small. Even after collection by the largest telescopes, they amount to as little as 10^{-16} W for a continuum source or 10^{-21} W for a weak spectral line. For this reason, the receiver must contribute a minimum of self-generated noise to the overall system and be highly gain stable in order to detect very small changes in noise power when the telescope is pointed at a RADIO SOURCE. In addition, it must be highly stable in frequency to detect narrowband spectral-line emissions and, when arrayed with other telescopes to form an INTERFEROMETER, must have a high degree of overall phase stability.

Modern radio astronomy receivers—general features

The modern radio astronomy receiver system can be divided into four main subsystems as depicted in figure 1. The first of these is a feed horn–front end combination situated at one of the focal regions of the telescope system. The front-end electronics will consist of low-noise preamplifiers for centimeter wavelength operation or a heterodyne mixer detection stage for millimeter wavelengths (for which amplifiers are not readily available). The output signal from the mixer will usually be at centimeter wavelengths and similar to the output of longer-wavelength receivers. The feed horns, amplifiers and mixers are integrated in such a way as to minimize transmission line loss between these elements, thus avoiding signal loss and excess noise. Finally, to reduce overall front-end receiver noise the preamplifiers, mixers and millimeter wave feed horns are all cooled to cryogenic temperatures.

The next part of the signal path employs the heterodyne mixing process again, where the amplified centimeter wavelength signals, or the down-converted millimeter mixer outputs, are converted to an intermediate frequency (IF) which can be more readily amplified. It is at this frequency that further signal conditioning such as filtering, gain control and detection can take place.

The principle of heterodyne detection can be understood by reference to figure 1. Here the received sky frequencies ν_{mm} and ν_{cm} are mixed in non-linear elements with local oscillator (LO) frequencies ν_{LOmm} and ν_{LOcm} to produce IFs ν_{cm} and ν_{IF}.

In fact, the mixing process produces many frequency products consisting of the sum, difference and all harmonic combinations of the signal and LO inputs. However, it is the difference frequencies which are selected by a filter and amplifier following the mixer, to produce the IF output band required. In any broadband mixer system, two input frequency bands will contribute to the signal content in the mixer IF output. These bands are given by $\nu_{LO} + \nu_{IF}$ and $\nu_{LO} - \nu_{IF}$, forming what is known as a double-sideband mixing system. This scheme was commonly used for millimeter-wavelength systems in years past; however, recent improvements in sideband rejection techniques allow single-sideband measurements to be made with most modern millimeter receiver systems. At centimeter wavelengths, which employ low-noise preamplifiers before the mixing process, filters can be used between the amplifier and the mixer to select the desired sideband for the mixer input.

The heterodyne mixing process requires an appropriate source of LO signal, and this forms the third subsystem necessary for the receiver. The LO system will provide all the necessary frequency sources at an appropriate power level to be mixed with the incoming sky signals and all the subsequent IF signals present in a multiple conversion receiver system. Frequency stability of these sources is paramount, particularly for spectral-line systems, and if the telescopes form part of an interferometer array, the phase behavior of these sources requires control along with a high degree of spectral purity and low phase noise.

A final signal subsystem deals with the output of the IF section in two ways. The first is to detect the IF power in a square law detector (a diode rectifier whose output dc voltage is proportional to the input IF power), integrate its output for a fixed integration time and then digitally record this output via an A–D converter. This output can then be calibrated as a measure of flux density.

The second method involves the use of a digital spectrometer to obtain a power spectrum of the final IF passband. This is done by first digitally sampling the IF noise waveform with sufficient speed and precision as to have minimal effect on the measurement accuracy. A digital CORRELATOR is then used to generate an autocorrelation function of the time-sampled IF noise, after which a Fourier transform is used to obtain the power spectrum. This spectrum is a direct representation of the spectrum at the incoming sky frequency, transposed by the various local oscillators used in the converter systems.

Receiver sensitivity

The contributions to excess noise in a practical radio astronomy system come from several sources which

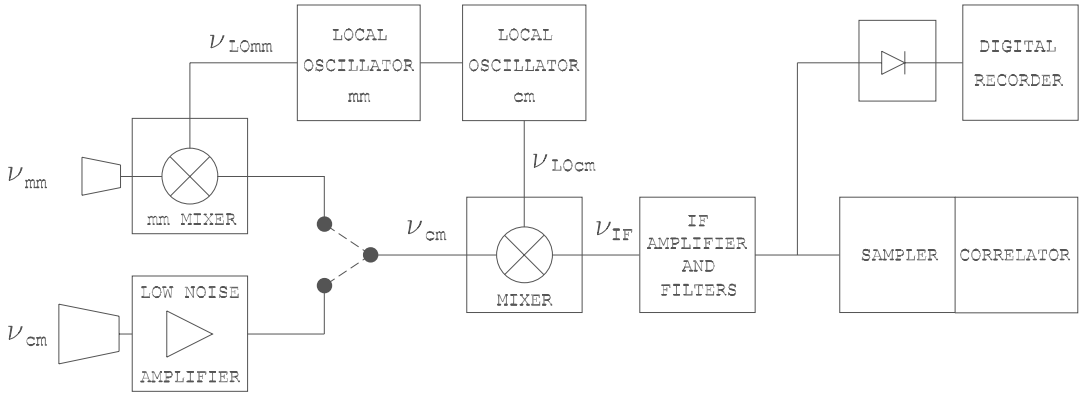

Figure 1. Block diagram of a typical radio astronomy receiver for both millimeter and centimeter wavelengths.

include atmospheric attenuation, antenna spillover and diffraction, feed horn and transmission line losses, as well as the receiver itself. The sensitivity of the receiver system depends on the level of this excess noise power. To quantify this, a figure of merit called the system temperature, T_{sys}, can be assigned to the receiver and telescope system. This is defined as the physical temperature of an ideal resistive termination, placed at the input of an ideal receiver with the same gain and bandwidth and producing the same noise power output as the practical system.

The minimum signal detectable against this noisy background is then defined by the radiometer equation, $\Delta T_{rms} \propto T_{sys}(B\tau)^{-1/2}$, where B is the final bandwidth just prior to detection and τ is the integration time. This expression indicates how important it is to minimize T_{sys} to obtain maximum sensitivity.

For frequencies of 1–300 GHz the values of T_{sys} range from about 12 K to ∼1000 K. Bandwidths can vary from 1 kHz for spectral-line measurements to several GHz for broadband continuum observations, while integration times vary from fractions of a second for strong time-varying phenomena to tens of hours for weak spectral lines.

The feeds

Reflector antennas need a feed horn or some other type of radiating element to couple the receivers to the reflector systems. For effective coupling the feed should be dual polarization, have low cross-polarization coupling, illuminate the reflector surfaces efficiently, have a highly circular beam and have sufficient bandwidth to match the receiver. Much development has occurred in feed-horn design over the years, starting with simple circular waveguide horns, progressing through choke-ringed aperture and early multiple-mode designs, to the modern corrugated hybrid-mode horn in its single- or dual-mode form. These corrugated horns are characterized by radial quarter-wavelength slots (operating frequency) in the walls of the waveguide along its length, and a short mode conversion section at the waveguide input end to excite the required hybrid mode. This mode, on radiation from the horn aperture, displays very low cross-polarization, excellent pattern symmetry and low sidelobe structure thus making it an ideal solution for radio astronomy application. A further development to this type of horn resulted in the internal corrugated surface being profiled to produce a more compact design, and this, when excited by a ring-loaded slot mode converter, produces a feed-horn system with an octave bandwidth. An excellent review of the design parameters of all these types of feed is given by Olver *et al* (1994).

A recent development in hybrid-mode feed design is the dielectric-loaded horn. This is a smooth-walled, profiled horn filled with a dielectric of appropriate permittivity. A small gap between the dielectric and horn wall allows the hybrid mode to propagate and, because there are no quarter wave slots, the potential bandwidth of this design is enormous. A recent design indicates a horn performance covering 16–120 GHz, with pattern symmetry, low cross polarization and high return loss being maintained over this wide frequency range.

For feed arraying applications such as focal-plane imaging arrays, while the corrugated horn is still the most efficient, its size makes it difficult to pack closely. Simpler horns, such as the Potter, stepped and diagonal horns, are better suited for these applications, such as multibeam horn arrays for fast surveying. Figure 2 shows smooth-wall stepped horns in a 13-beam hexagonal array, at 21 cm on a 64 m prime focus fed paraboloid.

Millimeter wave receivers

Most modern millimeter wave receiver systems will have a quasi-optical input beam waveguide, in which polarization splitting and LO power coupling can take place before the incoming radiation finally illuminates a lens-corrected feed horn. The feed horn will be closely integrated with a heterodyne mixer block, both of which will be cooled within a cryogenic vacuum dewar to 4 K. The horn coupling to the beam waveguide will be via a transparent vacuum window.

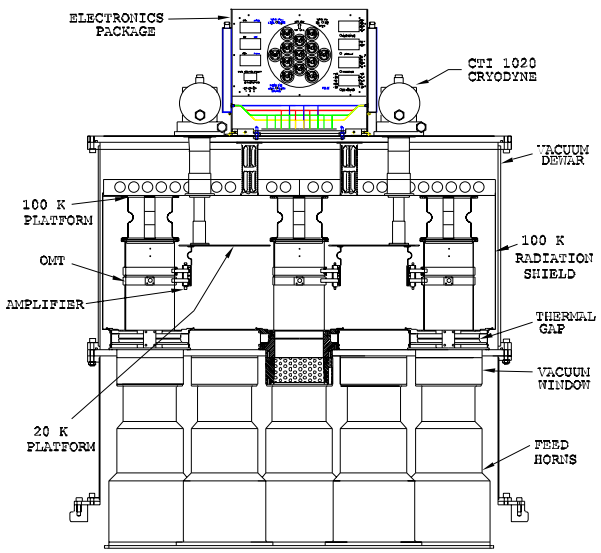

Figure 2. Cross-section view of a 21 cm multibeam front end consisting of a 13 stepped horn hexagonal array, cryogenic receiver dewar and cooled orthomode waveguide-coaxial transitions.

The non-linear element used in the heterodyne mixer is a superconducting tunnel-junction type or superconductor–insulator–superconductor (SIS) junction. Mixers utilizing these devices have very low noise temperatures and because of this have replaced gallium arsenide (GaAs) Schottky diode mixers in almost all of the millimeter wave systems currently operating. In practice the single-sideband (SSB) noise temperature of the best SIS receivers will be less than 0.5 K GHz^{-1} across the whole millimeter spectrum. Early tuning of these mixers was accomplished by adjustable backshorts in the waveguide structure. However, current mixer designs now achieve broadband tuning by integrated tuning circuits using thin film inductances to resonate the SIS junction capacitance.

Because the LO power required by SIS mixers is quite small ($\sim$1 μW), coupling to the junctions can be made either via the beam waveguide system through the feed horn or by $-$20 db directional coupler between the feed horn and mixer block. Sources of LO are now derived directly from phase-locked Gunn oscillators for the longer millimeter wavelength systems in the 1 cm–2 mm region or Gunn oscillator–multiplier combinations for wavelengths in the 1 mm region.

A significant development in recent years has been the rapid development of low-noise high electron mobility transistor (HEMT) amplifiers with good performance in the millimeter-wave region.

The availability of robust indium phosphide (InP) HEMT devices has now resulted in reliable hybrid 'chip and wire' amplifiers being developed, to operate at frequencies up to 110 GHz, with noise temperatures of 50 K when cooled to a physical temperature of 15 K. Monolithic microwave integrated circuit (MMIC) amplifiers also using InP, and designed to operate over the 75–110 GHz band, have also recently been tested at 15 K physical and found to yield amplifier temperatures of 50–60 K. This makes these low-noise amplifier systems competitive with SIS mixer receivers at frequencies up to 115 GHz, with the added advantage of a much simpler cryogenic cooling system.

Centimeter wavelength receivers

Centimeter wavelength receiver systems are characterized by preamplification of the incoming sky signal in a low-noise amplifier (LNA) before heterodyne mixing to a lower IF. The LNA is almost universally cryogenically cooled (except for frequencies below 1 GHz where cooling is not necessary) and utilizes GaAs HEMT amplifiers for frequencies up to $\sim$10 GHz and more recently InP HEMT amplifiers for frequencies up to 45 GHz. Cooled noise temperature performance of these LNAs is excellent, being in the region of 1 K GHz^{-1} for GaAs HEMT amplifiers and $<$0.5 K GHz^{-1} for InP HEMT amplifiers. The feeds used with these receivers are almost exclusively corrugated hybrid mode horns giving maximum efficiency with the telescope system, minimum spillover noise and good pattern symmetry for precision polarization measurements. In addition, wide bandwidths can be achieved by using the profiled form of corrugated feed.

While these centimeter feeds are often much too large to cool cryogenically, the transmission lines between the feed and LNA often are cooled cryogenically, so the feed horns must be integrated with the cryogenic dewar. Figure 3 illustrates this, showing a receiver–feed horn combination spanning 2 cm–3 mm wavelength and utilizing three horns of the compact corrugated profiled form. The linear polarization splitters, and following InP HEMT amplifiers for all three receivers, are incorporated within the cryogenic dewar and cooled to a physical temperature of 15 K.

The heterodyne mixer and IF systems following these centimeter front ends are now simple and straightforward. Wide-bandwidth balanced and double-balanced diode mixers are readily available with operating wavelengths up to 1 cm (30 GHz). The LO power requirements for these mixers is readily obtained from YIG (yttrium iron garnet) tuned transistor oscillators or dielectric resonator oscillators, phase locked to a reference frequency derived from an atomic standard oscillator.

A novel development in recent years has been the use of optical-fiber transmission systems to distribute these LO reference frequencies within the telescope and across arrays of telescopes. Fiber systems have also been used to transport band-limited sky signal noise from remote antenna front ends and to distribute IF signals within a telescope system.

Future developments

The impetus for future radio astronomy receiver development will be driven by all types of arraying applications.

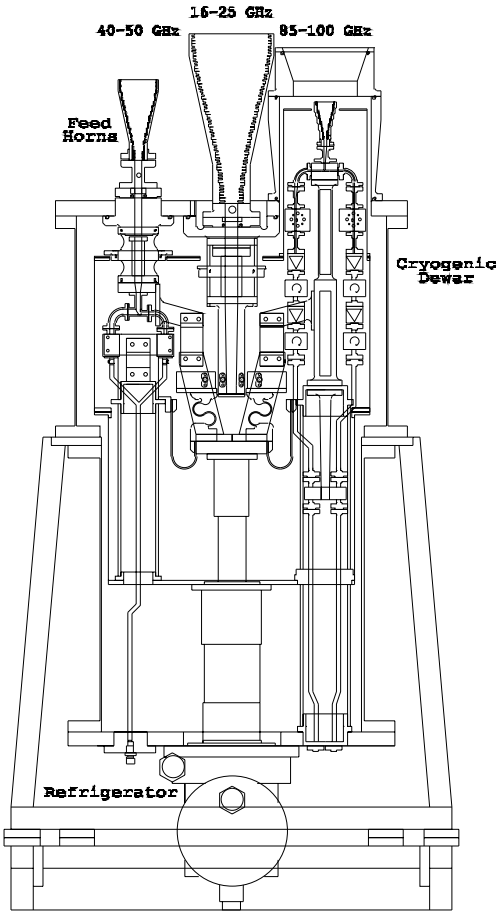

Figure 3. Wideband front end utilizing compact corrugated feed horns. Frequency selection is accomplished by feed horn translation to the antenna Cassegrain focus.

Focal-plane feed arrays will require close-packed feeds backed by compact receivers to image the focal-plane region of single paraboloids, while distributed arrays of large collecting area will require very large numbers of sensitive, wideband, reliable and inexpensive receivers.

These challenges will best be met by having all parts of the basic receiver subsystems in the form of MMICs. Already tentative steps are being taken to develop low-noise amplifiers, heterodyne mixers and oscillators in this form for both centimeter and millimeter bands, leading to the possibility of a complete 'receiver on a chip' in the very near future. A successful integration of these devices, combined with fiber-optic connections between elements, will be a major step forward towards developing large-area arrays.

Receivers: Submillimeter Feeds and Receivers

The submillimeter band of the ELECTROMAGNETIC SPECTRUM is generally defined as wavelengths in the range 1 mm–100 μm. This spectral range is at present only partially explored owing to molecular (H_2O and O_2) absorption in the Earth's atmosphere. Also, it is difficult to extend the performance of radio-style telescopes to this band. Finally, it is still early in the development of both continuum detectors, usually bolometers, and heterodyne, or radio, detectors, which are used for high-resolution spectroscopy. It is the latter devices which form the subject of this article.

The submillimeter band contains several important aspects of astrophysics, e.g. the spectral features of the rotational motion of interstellar molecules such as CO and CH_3OH and the fundamental lines of light, hydride molecules such as H_2O, NH_3, HCl and HF. The band also contains the ground state fine-structure lines of atoms and ions, e.g. atomic carbon [C I]. The interstellar medium also contains dust, seen in the continuum, and the combination of spectral and continuum data provides information which enables the study of STAR FORMATION in our Galaxy. The submillimeter band naturally contains emission mostly from objects whose temperatures range from about 10 to 100 K. This is indeed the temperature range of much of the interstellar medium of our Galaxy but is also the temperature of the redshifted, but intrinsically hotter, gas and dust in distant galaxies. This means that much of the information about distant galaxies, now seen to $z \sim 5$, comes to us in the submillimeter band (see MILLIMETER AND SUBMILLIMETER ASTRONOMY.

Astronomy demands the very best possible receivers to detect the limited number of photons arriving from such distant objects. Several new facilities are under construction or in the design and development phase, complementing existing facilities such as the CALTECH SUBMILLIMETER OBSERVATORY and JAMES CLERK MAXWELL TELESCOPE. These include the Smithsonian interferometer on Mauna Kea, ALMA, the international interferometer planned for the Atacama desert in Chile, SOFIA, the US–German airborne observatory, and FIRST, the ESA–NASA space observatory.

Receiver principles

The operation of a heterodyne receiver in the submillimeter is similar to that for a radio receiver. The basic principle is to mix the weak signal ($E_1 \cos \omega_1 t$) from the telescope with a strong local oscillator signal ($E_2 \cos \omega_2 t$) in a non-linear element, so generating the difference term $E_1 E_2 \cos(\omega_2 - \omega_1)t$ of much greater power than E_1^2 and at the frequency $\omega_2 - \omega_1$, which is determined by the frequency range of the preamplifier. The amplified intermediate-frequency (IF) signal, say 1–2 GHz, is finally integrated in small frequency intervals, say 1 MHz, with the aid of some kind of spectrometer, such as a FILTERBANK, CORRELATOR etc.

Traditionally the receiver acquires the radiation from the telescope by means of a feed horn which condenses the free space wave from the telescope down to a waveguide mode. The feed horn is usually of the type known as a 'scalar' feed, which has the property of generating an approximately Gaussian beam of the same width in both dimensions. It does this by means of circular grooves inside the cone which act as a high-impedance boundary. The radiation is then fed from the horn to the mixer element by a short run of rectangular waveguide (see figure 1). The leads providing the current through the mixer will be across the waveguide in the strong electric field region for the TE_{01} mode. Sometimes the mixer element may be matched to the waveguide by mechanical tuners, or better by microcircuit elements, photolithographically fabricated. An alternative scheme for coupling radiation to the mixer element is 'quasioptical', which avoids the difficulties in construction and alignment associated with very high-frequency waveguide. Here a high dielectric constant material plano-convex (hyperhemispheric) lens focuses the radiation to a planar microantenna on a flat substrate fixed to the flat side of the lens. (See figure 2). The planar antenna, which feeds current to the mixer, can take many possible forms, such as bow-ties, spirals, dipoles or slots. The best results have been obtained with twin slots, where the beam profiles are similar to those for scalar feed horns.

The critical element in the receiver, and the one which usually gives the receiver its name, is the mixer. This may be a classical diode, typified by the Schottky barrier elements formed from photolithographically shaped gold dots on gallium arsenide substrates, or a quantum detection device, usually involving a superconductor, such as a Josephson junction or a quasiparticle tunneling junction. These last two devices are based on a superconducting phenomenon, the tunneling of Cooper pairs and single quasiparticles respectively, both of which can occur in the physical structure of a superconductor–insulator–superconductor (SIS) tunnel junction (see DETECTORS: SUPERCONDUCTING TUNNEL JUNCTION DEVICES). For better or worse, the name 'SIS mixer' is now applied to the device in use in nearly all high-frequency RADIO TELESCOPES in the world, which is the single-quasiparticle, photon-assisted tunneling device (an early attempt to introduce the acronym SQPAT failed).

There is a certain similarity between a semiconducting photoconductor device and an SIS device in that, in both cases, an incoming photon causes a transition of an electron (or quasiparticle) from a state below an energy gap to a state above, where conduction occurs. The essential difference is that the semiconductor energy gap is about 0.6 eV, suitable for optical–infrared photon detection, whereas the superconducting gap is $\sim 10^{-3}$ eV, equivalent to a submillimeter photon's energy. This is the reason for choosing SIS devices for frequencies of detection up to the energy gap of the superconductor (about 2.9 meV = 700 GHz for Nb—the most suitable material found to date).

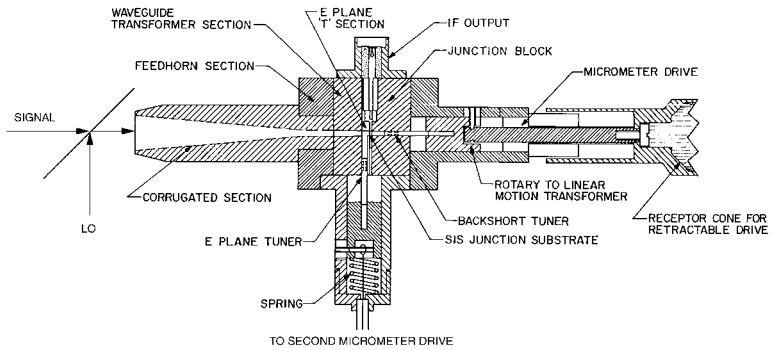

Figure 1. The structure of a typical submillimeter waveguide SIS receiver. The case shown has beamsplitter LO injection, a scalar feed and E-plane and backshort tuners.

Actually, it is not required that the mixer element be a diode-type device; it is only necessary that the mixer element have a non-linear I–V characteristic. The device can even be bulk material and in fact the first successful heterodyne receiver in the submillimeter employed an InSb hot electron bolometer (HEB) element as mixer, in the form of a rod across the waveguide. The problem with such devices is that there is a relatively slow response of the hot electron current due to the weak electron–phonon coupling and, in the InSb receiver case, it is limited to about 1 MHz. Such a narrow-band device would not be considered useful today. Surprisingly, a new style of HEB employing a very small (micron-size) superconducting film is having considerable success and is almost certainly the device of choice for frequencies well above the band gap of niobium.

A measure of the effectiveness of a receiver is the noise temperature ($T_{\rm n}$). That is the temperature of a blackbody (in the Rayleigh–Jeans approximation) which, when coupled fully to the input of the receiver, produces the measured noise at the output. All receivers are governed by the Dicke radiometer equation, where the signal-to-noise ratio is given by:

$$S/N \approx \frac{T_{\rm A}^*}{T_{\rm n}}\sqrt{\Delta\nu\Delta\tau}.$$

$T_{\rm A}^*$ is the Rayleigh–Jeans temperature of an astronomical emission object, $\Delta\nu$ is the channel width which is being integrated and $\Delta\tau$ is the integration time. In general a receiver will have two sidebands [upper $(\omega_2 - \omega_1)$ and lower $(\omega_1 - \omega_2)$]. $T_{\rm n}$ is usually measured by replacing $T_{\rm A}^*$ with known temperature loads and, if both sidebands are equally sensitive, then $T_{\rm n}$ is the double-sideband (DSB) value, relevant to continuum detection. For spectroscopy, where the astronomical line of interest falls in only a single sideband (SSB), the relevant noise temperature to employ in the Dicke formula will be $T_{\rm n}({\rm SSB}) = 2T_{\rm n}({\rm DSB})$.

A non-trivial component of a submillimeter receiver is the source of local oscillator (LO) power, which has to be adequately intense and stable. This becomes an extreme technological challenge when applied to a receiver operating at 1000 GHz (1 THz) or more. The LO power required by a submillimeter receiver varies depending on the type of detector element and the frequency. LO power is coupled to the receiver either by means of a dielectric beamsplitter, which must allow most of the signal to pass and therefore couples only a small fraction of the LO power, or by means of a frequency selective device such as an INTERFEROMETER. A balanced mixer configuration is also a possibility. Roughly speaking, in most cases the LO power needed is the same order of magnitude as the dc power supplied by the bias circuit, because the device is in thermodynamic equilibrium somewhere between the sinks of the dc and LO supplies, to which it is coupled. The typical superconducting device will require a bias voltage of ∼2.5 mV (related to the gap voltage), whereas a semiconducting device needs a bias of ∼0.5 V. Since both devices must have a suitable circuit impedance (∼100 Ω), the superconducting device should require roughly 4 orders of magnitude less LO power, making it the device of choice in this respect. The LO power is usually generated by a series of diode varactor doubler or tripler units multiplying the output of a phase-locked Gunn oscillator.

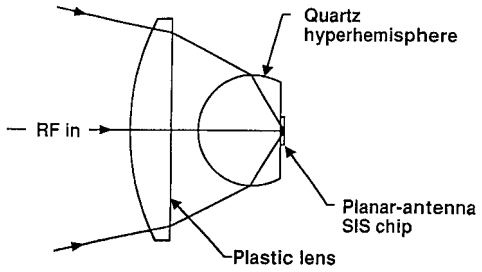

Figure 2. A quasioptical coupling scheme for an SIS receiver. The LO could be injected as in figure 1, but the waveguide components are all replaced with optical systems. The two-lens design shown here can be replaced with a single silicon lens suitably antireflection coated.

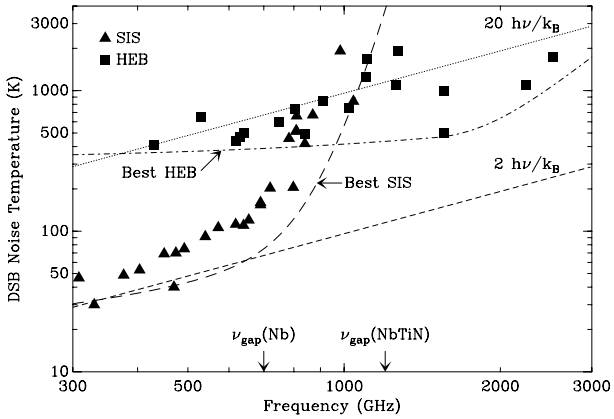

Figure 3. Noise temperatures for SIS receivers (triangles) and HEB receivers (squares) compared with the quantum limit.

The SIS receiver

The SIS receiver is now the workhorse for millimeter and submillimeter observatories. Originally, when the SIS junctions were first introduced they were made from a lead–indium–gold alloy which suffered mechanical and chemical problems and was unreliable. Now the junction elements are usually made from niobium, which is robust and provides a high degree of reliability. It is expected that the order of 1000 such receivers will be constructed for the ALMA project.

Clearly, the requirement for the receiver is that it provides the best S/N in a given observation, so in the Dicke formula $T_{\rm n}$ must be minimized. $T_{\rm n}$, the noise from the receiver, is limited by the quantum noise due to the detection of photons with simultaneous measurement of phase and amplitude. This fundamental noise source provides a minimum noise temperature of $T_{\rm n} \sim h\nu/k$ where h is Planck's constant and k Boltzmann's constant. To this are added excess noises from the inefficiency of the frequency conversion process, noise from the preamplifier and noise due to signal loss in the warm input optics. SIS receivers are able to achieve $T_{\rm n}$ values only a few times the quantum limit throughout the millimeter and submillimeter bands, up to the gap frequency of niobium. Above this frequency a microstrip circuit made from niobium becomes lossy. A plot of the noise temperature of receivers including a set of niobium junction SIS receivers is shown in figure 3.

A second factor in the performance of the receiver is the IF bandwidth which is primarily limited by the achievable bandwidth of low noise cryogenic HEMT preamplifiers. This is currently about 10 GHz but is expected to increase further yet. The third factor is the integration time which can be achieved before the system noise ceases to integrate down with the square root of time. This depends on the care taken in thermal stabilization of components, for example, the integration channel width and the type and rate of switching in use.

In order to extend the low-noise performance achieved below the niobium gap to higher frequencies, there are several possibilities. One is simply to use higher-gap superconducting material for the microstrip circuit. Niobium titanium nitride has been successfully used. However, that solution is limited by the band gap of high-quality superconductors (see figure 3). A completely different superconducting device, which is not limited in frequency by the band gap, is the HEB. In principle this is similar to the older bulk semiconductor device, but has a much shorter response time and therefore should be more useful in a practical device.

The superconducting hot electron bolometer

SIS receivers are the devices of choice for most applications, when they are operating below the gap frequency. For higher frequencies the choices are between SIS receivers with normal metal tuning circuitry, which extends the range for SIS receivers to about 1200 GHz, Schottky diode receivers, which are generally more noisy but operate to several THz if sufficient LO power is available, and superconducting HEB receivers, which also have performance to several THz, but are relatively low noise and require less LO power than do SIS receivers. For astronomy applications such as the ESA–NASA submillimeter space telescope, FIRST, and the US–German airborne telescope project, SOFIA, the choice for frequencies above 1200 GHz may be the HEB.

HEBs use a heating-induced non-linearity in a small superconducting film held near the critical temperature, T_c. The electronic system is heated above the lattice temperature by dc and rf power. The device will act as a mixer as long as the IF is restricted to the regime below the hot electron relaxation rate, otherwise the electron temperature cannot follow the power variation at the IF. There are two types of superconducting HEB, the first depending on the electron–phonon interaction for cooling the hot electron system and the second using the diffusion process to carry the excess thermal energy out of the superconductor and into the normal metal leads. Both techniques appear to work well, with the diffusion type able to sustain IF bandwidths of about 10 GHz for niobium films. The plot of figure 3 includes the HEB results for very high frequencies.

However, the development of SIS receivers came partly as a result of the intense effort in the late 1970s to develop superconducting switching devices for computers, using the Josephson effect. Although this was never successful for computing, it provided materials and a fabrication technology for making small-area superconducting tunnel junctions. The first SIS detectors were described in adjoining papers in 1979 by Berkeley and Bell Telephone Labs groups working independently:

Red Dwarfs/Flare Stars

The red dwarf stars are main-sequence stars characterized by masses in the approximate range from $0.51M_{\odot}$ to $0.08M_{\odot}$. The upper mass limit corresponds to a spectral type of M0 V and the lower limit is the critical mass for the onset of nuclear burning in the central cores of stars with chemical abundances similar to the Sun. Below the range of approximately $(0.074–0.08)M_{\odot}$ is the realm of substellar objects known as *brown dwarfs*. The radii of the red dwarfs span from $0.60R_{\odot}$ to $\approx 0.18R_{\odot}$ while their effective temperatures are in the approximate range 2500 K–4000 K. Thus, the red dwarf stars are cooler, smaller and less massive than the Sun. Correspondingly, their luminosities are low relative to the Sun, ranging from less than a few tenths of a per cent (or less) to about 8% of the solar luminosity. The flare stars are observationally defined as those red dwarfs that exhibit transient brightenings on time scales of seconds to minutes as seen in the visible region of the electromagnetic spectrum. These short-lived brightenings are considered to be qualitatively similar to SOLAR FLARES.

The red dwarfs represent the largest constituent of the STELLAR POPULATION, composing at least 80% of the stars in the Galaxy. Therefore, the typical star in the Galaxy is smaller, less massive and cooler than the Sun. From this perspective, the Sun is not a common star. Rather, the Sun and Sun-like stars are actually atypical compared with the more numerous red dwarf stars. The large mass-to-luminosity ratios of the red dwarfs combined with their high flare activity and relatively large space density suggest that these objects could play an important role in galactic dynamics.

Within K–M spectral types, the red dwarfs are divided into subclasses according to the appearance of certain spectral features. In particular, the dMe stars are those red dwarfs that exhibit Hα line emission. It is nearly always the case that a given dMe star is also a flare star. Those red dwarfs without Hα in emission are non-dMe stars or, simply, dM stars. The spectrum of a dM star exhibits either Hα in absorption or no apparent Hα feature. Flare activity has only rarely been observed in dM stars, and these objects are usually not identified as flare stars.

Interior and atmospheres

The interior structure of red dwarf stars is characterized by a thick outer convection zone relative to the radius of the star. STELLAR INTERIOR models suggest that at a mass of $0.4M_{\odot}$, the depth of the convection zone is nearly 60% of the stellar radius. At masses less than approximately $0.30M_{\odot}$, the interiors of red dwarfs are completely convective. The photospheric spectra of red dwarfs are dominated by molecular features. Molecular bands of TiO and, for the latest types, VO are strongly present together with atomic lines of Ca II, Na I and K I. The progression from K to M dwarfs is characterized by increasing strength of TiO absorption. The coolest M dwarfs (later than M7 V) exhibit prominent absorption by VO. Bands of MgH are visible in K through early M dwarfs ($\sim$ M3.5) after which they become dominated by overlying TiO. Bands of CaOH at 553–557 nm and near 625 nm begin to appear at spectral type M3.5. These bands become especially prominent toward the latest M dwarfs (at least as late as M8) where they remain visible through the thicket of TiO lines. The CaH B band at 638.5 nm is also sensitive to temperature, first appearing at spectral type M0 and remaining identifiable through the latest M spectral subclasses. Atomic lines of Fe I and Ca II that are strong in the K through mid-M dwarfs disappear in the coolest M dwarf stars as molecular absorption by TiO and VO dominates. The appearance of the red spectrum of these cool dwarfs is illustrated in figure 1.

The red dwarfs can exhibit periodic or quasi-periodic behavior in their photometric light curves. This is due to the rotational modulation of large, cool spots analogous to SUNSPOTS, on the surfaces of these stars. As rotation carries a spotted region on the star through the line of sight, a dip in the photometric light curve is observed. Repeated observation of this phenomenon yields the rotation period of the star, independent of the inclination of the rotation axis to the line of sight. The rotation rates of red dwarfs are correlated with their activity in the form of flares, emission lines and x-ray emission from a CORONA. Red dwarfs with rotation rates exceeding 3–5 km s^{-1} are generally more active and tend to be classified as dMe stars. Those objects with slower rotation rates are non-dMe or, simply, dM stars. These red dwarfs have lower levels of magnetic-field-related activity and no Hα emission.

All red dwarfs thus far observed with sufficient sensitivity and spectral resolution exhibit Ca II H and K line emission, indicative of the presence of CHROMOSPHERES. In addition to Ca II resonance line emission, ultraviolet spectra obtained with satellite observatories have revealed Mg II h and k line emission as well. Emission from these metal species together with Hα emission (as seen in the dMe stars) establishes the presence of significant nonradiative heating in the red dwarfs that is presumed to be related to surface magnetic fields. Interestingly, chromospheric models have shown that Hα absorption is also a result of chromospheric heating in the non-dMe (dM) stars. The photospheres in these red dwarfs are so cool that, in the absence of a chromosphere, only weak Hα absorption would be observed in their spectrum. However, as chromospheric heating increases, the population of hydrogen atoms in the $n = 2$ quantum level increases, thus leading to increasing opacity in the Hα line to initially produce an absorption feature. From the perspective of stellar chromospheric activity, this result suggests that the principal difference between dMe and dM stars is, in part, due to differing intrinsic heating rates that are present in their respective chromospheres.

The far-ultraviolet spectrum of active red dwarfs is dominated by emission lines arising from high-temperature ($T > 50\,000$ K) plasma in the so-called transition region of the outer atmosphere. Distinctive spectral features include lines arising from C IV, Si IV

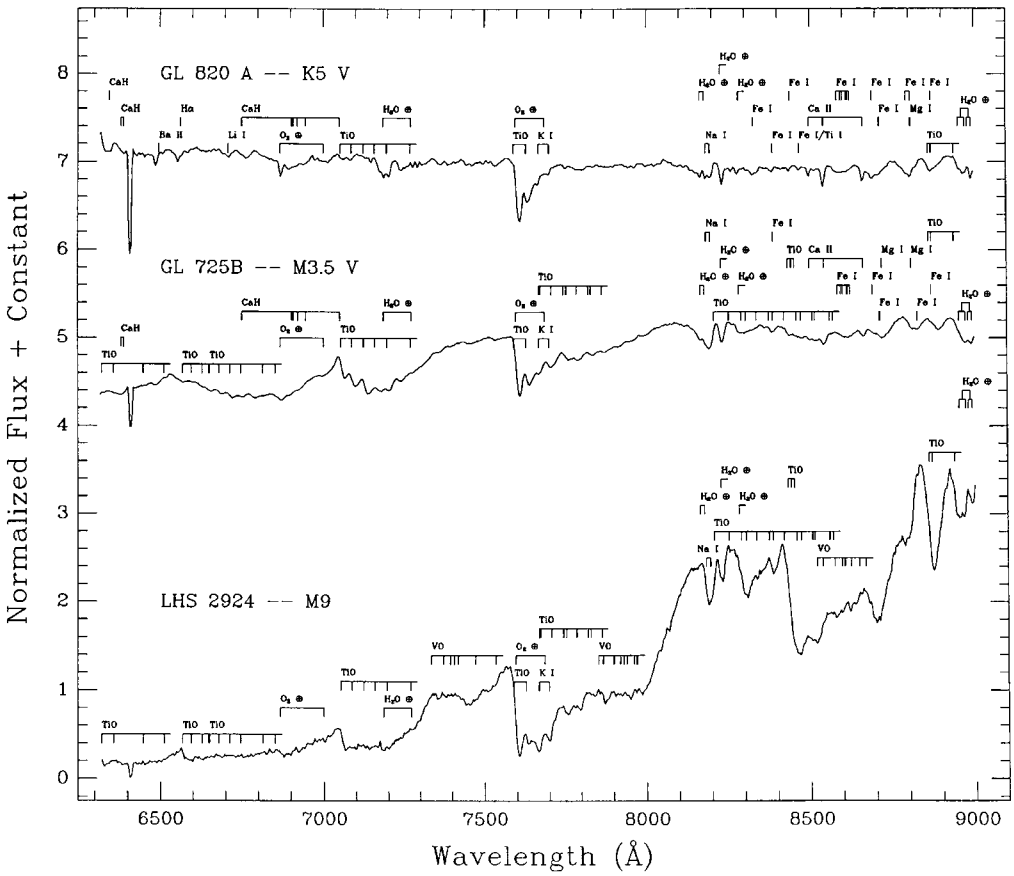

Figure 1. Photospheric spectra of red dwarfs. Illustration of the principal features in the red spectrum of cool dwarf stars extending from spectral types mid-K to M9. Molecular bands of titanium oxide (TiO) begin to dominate the spectrum in the M dwarfs while, in the coolest dwarfs, vanadium oxide (VO) becomes prominent. Other features include CaH and neutral metal lines of iron (Fe), magnesium (Mg) and sodium (Na). Terrestrial lines due mainly to atmospheric water are indicated with a ⊕ symbol. (From Kirkpatrick J D, Henry T J and McCarthy D W Jr 1991 *Astrophys. J. Suppl.* **77** 417.)

and N V. The surface fluxes of these high-temperature lines in the dMe stars are 10–100 times greater than the corresponding line surface fluxes in the quiet Sun. The far-UV spectra of the less active red dwarfs (dM stars) are, by contrast, dominated by lines arising from neutral metal species and other low-temperature features. An illustration of the far-ultraviolet spectra of active and inactive red dwarfs is given in figure 2.

X-ray emission and coronae in red dwarfs

The red dwarfs are x-ray sources with levels of detected x-ray emission that range in luminosity from ∼0.1 to ∼1000 times that of the value of the quiet solar corona (∼10^{27} erg s^{-1}). The absolute x-ray luminosity of red dwarfs declines toward lower masses. However, the x-ray luminosity normalized to the bolometric luminosity of the star, which is often expressed as L_x/L_{bol}, can persist among the active (dMe) stars at the so-called saturation level of approximately $L_x/L_{bol} \simeq 10^{-2.5}$ to spectral types at least as late as M7. Thus, the active red dwarfs are characterized by relatively high coronal heating efficiencies compared with that of the active Sun (i.e. the Sun as viewed in the x-ray at the maximum of the solar activity cycle) where, for the active Sun, we have that $L_x/L_{bol} \sim 10^{-6}$. If there is any sharp decline in coronal heating efficiency, as measured by the parameter L_x/L_{bol}, then it occurs at spectral subtype M8. However, any possible decline in coronal heating efficiency cannot be verified until more red dwarf stars of subtypes M8 and M9 are discovered and observed with an x-ray telescope such as the new Chandra x-ray satellite observatory.

Analysis of the x-ray results shows that those red dwarfs that are more luminous in the x-ray have higher average coronal temperatures. Red dwarfs that exhibit little chromospheric activity (i.e. dM and dK stars) do indeed have cooler and weaker coronae than the more active (dMe) stars. Detailed model results based on x-ray observations reveal that the coronae of the low-mass dwarfs consist of two distinct thermal components: a so-called 'soft' component with temperatures $T \sim$ (2–4) $\times 10^6$ K and a 'hard' component with $T \sim 10^7$ K.

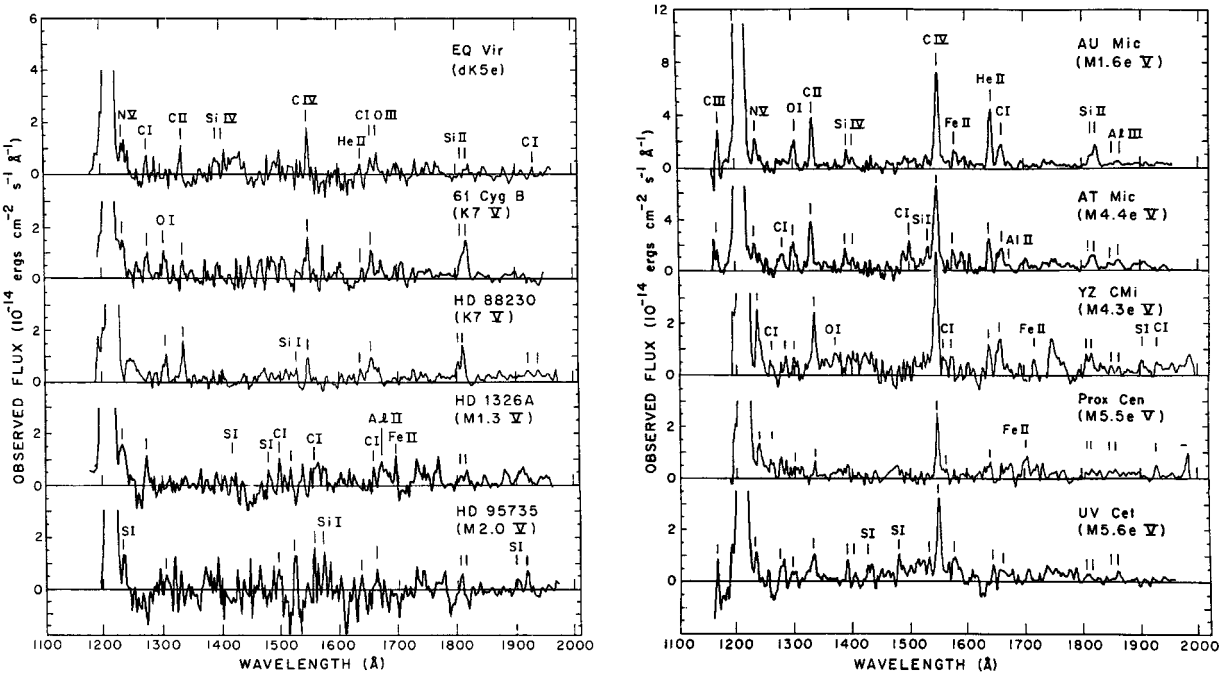

Figure 2. Far-ultraviolet spectra of red dwarfs and flare stars. The far ultraviolet spectra of active and inactive red dwarf stars as obtained with the International Ultraviolet Explorer satellite observatory. The identification of emission lines is indicated. The active red dwarfs (denoted as types dKe or dMe) exhibit emission features from highly ionized species, indicative of hot plasma. By contrast, the far UV spectra of the inactive (dK or dM) red dwarfs are dominated by emission from low-temperature species thus implying that a significantly lower density of hot plasma is present in their outer atmospheres. (From Linsky J L, Bornmann P L, Carpenter K G, Wing R F, Giampapa M S, Worden S P and Hege E K 1982 *Astrophys. J.* **260** 670.)

Based on the observational and model results, the author and his collaborators concluded that coronal emission in active red dwarfs (dMe stars) can be interpreted as arising from quiescent active regions (a quiescent, low-temperature component) and compact flaring structures (variable, high-temperature component).

Active red dwarfs are also radio sources. The quiescent component of radio emission is attributed to gyrosynchrotron radiation from electrons with energies of 20–200 keV. Surveys of both radio and x-ray emission reveal that the x-ray and radio luminosities are directly correlated over a range of 3 orders of magnitude, irrespective of spectral type. This result strongly suggests that there is a physical relation between the particle populations that give rise to the x-ray and to the radio emissions.

Underlying the wealth of activity that is observed in red dwarfs are magnetic fields. Emergent magnetic flux as a result of interior dynamo action is presumably directly related to the origins of spotted regions, flares, chromospheres and coronae, as is seen on the Sun. Direct spectroscopic detections of surface magnetic flux on active red dwarf (dMe) stars reveal field strengths in the broad range of 2–4 kG covering over 50% of the star. These kinds of field strengths are consistent with a model consisting of magnetic flux tubes in equilibrium with the surrounding photospheric gas pressure. Direct measurements of magnetic field properties in the relatively inactive red (dM) dwarfs have not yet been accomplished.

Flare activity in red dwarfs

The vast majority of observations of flare outbursts in red dwarf flare stars have been recorded in broad-band photometry, typically with Johnson UBV filters. During a flare, the U band exhibits a larger relative change than the B band which, in turn, shows a larger relative change than the V band. The blue color of the optical flare energy distribution is due both to enhanced UV emission lines and to a continuum suggestive of an optically thick, radiating plasma which is much hotter than the underlying red dwarf photosphere. The continuum emission in stellar flares is consistent with free–free emission at temperatures of (5–10) $\times$ 10^4 K, bound–free emission at a temperature of 2 $\times$ 10^4 K, or a combination of both processes. A black-body component due to heating of the lower stellar chromosphere and upper photosphere with a characteristic effective temperature of $\sim 10^4$ K may also contribute to the flare continuum emission. Based on the assumption that the flare continuum emission is predominantly composed of black-body radiation, effective areas of the flaring region are derived that correspond to a range from 0.5% to 2% of the stellar disk.

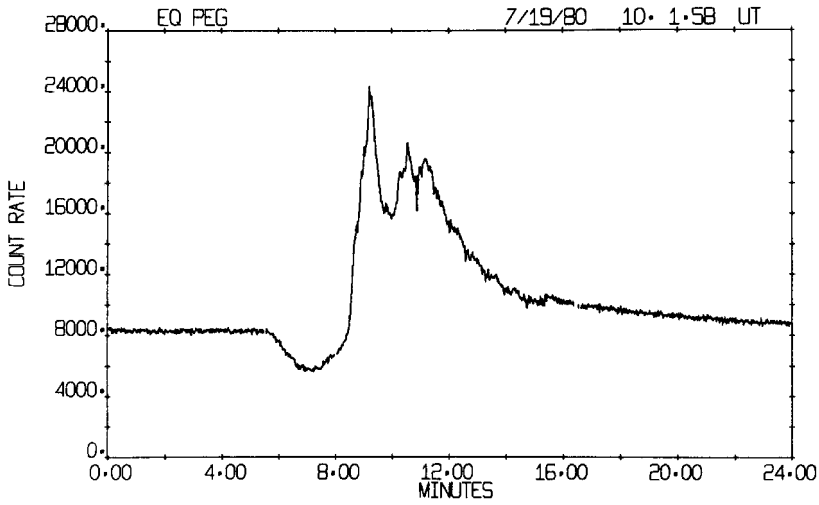

Figure 3. Flare event on a red dwarf flare star. A particularly striking example of the variety of phenomena that can be seen in stellar flares is encapsulated here in a single, extraordinary event observed on the binary flare star EQ Pegasi (dM3.5e + dM4.5e). This event was observed at the Cloudcroft Observatory 1.2 m utilizing high-speed photometry in the Johnson U band filter. The flare is preceded by a 'pre-flare dip', i.e. a decrease in the U band brightness of the star, in this case, of roughly 0.1 mag min^{-1} for 2.7 min. The signal then leveled off at 75% of the quiescent brightness for 1 min before the flare begins. The peak of the flare is 3 times the quiescent level brightness, and is followed by two more smaller peaks separated by 60 and 30 s. The flare event then decays exponentially in brightness, finally returning to the pre-flare level 19 min after the onset of the event. (From Giampapa M S, Africano J L, Klimke A, Parks J, Quigley R J, Robinson R D and Worden S P 1982 *Astrophys. J. Lett.* **252** L39.)

The total energy released during a stellar flare event can be as much as 2–3 orders of magnitude greater than the largest solar flares.

Photometric observations of stellar flares display a wealth of variety in temporal profile and color. Generally, however, the flares are divided into two categories: 'spike flares' typically attain their peak intensity in less than a minute while 'slow flares' take several minutes before reaching maximum. The initial decay toward quiescence is rapid, falling below half-maximum in several minutes. In most flares the rate of decay quite suddenly slows and then can take several hours to relax fully to quiescence. Large flares typically exhibit the superposition of slow and fast events that may be the result of several related flares, or a 'wavelike' flaring in the stellar active regions. A distinctly non-solar-like phenomenon that occasionally occurs in flare stars is a 'pre-flare dip'. A particularly striking example of this sudden diminution in the light from the star, followed by a flare, is shown in figure 3.

Time-resolved, optical spectroscopic observations of red dwarf flares reveal that a strong continuum rises to dominate the violet and blue region during maximum light. The Balmer series is seen out to H14, Ca II H and K emission, and He I emission lines all rise with the continuum, but usually peak a few minutes afterwards. The rapid decline of the continuum is responsible for the initial photometric decay, while the emission lines slowly return to quiescence. The emission lines can remain at enhanced levels for hours following the initial flare outburst and decline. A sequence of spectra obtained during a flare on the prototype flare star, UV Ceti, is displayed in figure 4.

High-resolution line profiles obtained during flares can show evidence of significant mass motions with blueshifted emitting material rising at $\sim$70 km s^{-1} in one case, and perhaps much higher velocities in other cases. In brief summary, the qualitative picture of the flare would include upward-moving material filling a large volume (with a characteristic length scale $\sim$0.1 stellar radius) with hot plasma at chromospheric densities of $n_e \sim 10^{11-12}\,\text{cm}^{-3}$. The flare volume produces line emission that is strongly enhanced in total flux compared with the pre-flare emission but is often otherwise similar in basic line profile shape to the profile in the quiescent chromosphere (apart from components that can be attributed to bulk motions in the line of sight). The flare luminosity can be a few per cent of the quiescent stellar bolometric luminosity which is an order of magnitude greater than the corresponding ratio for either chromospheric or coronal heating. Hence, the conversion of flare energy to radiative flux is significantly more efficient than the processes that control coronal and chromospheric heating in red dwarfs and flare stars.

Observations of stellar flares in the x-ray reveal that the total energy in soft x-rays is often comparable with that in the largest solar flares. Stellar flare x-ray light curves morphologically resemble the x-ray light curves observed for compact and two-ribbon flares that occur on the Sun. Very recent observations by the author and his collaborators using the ROSAT x-ray satellite observatory

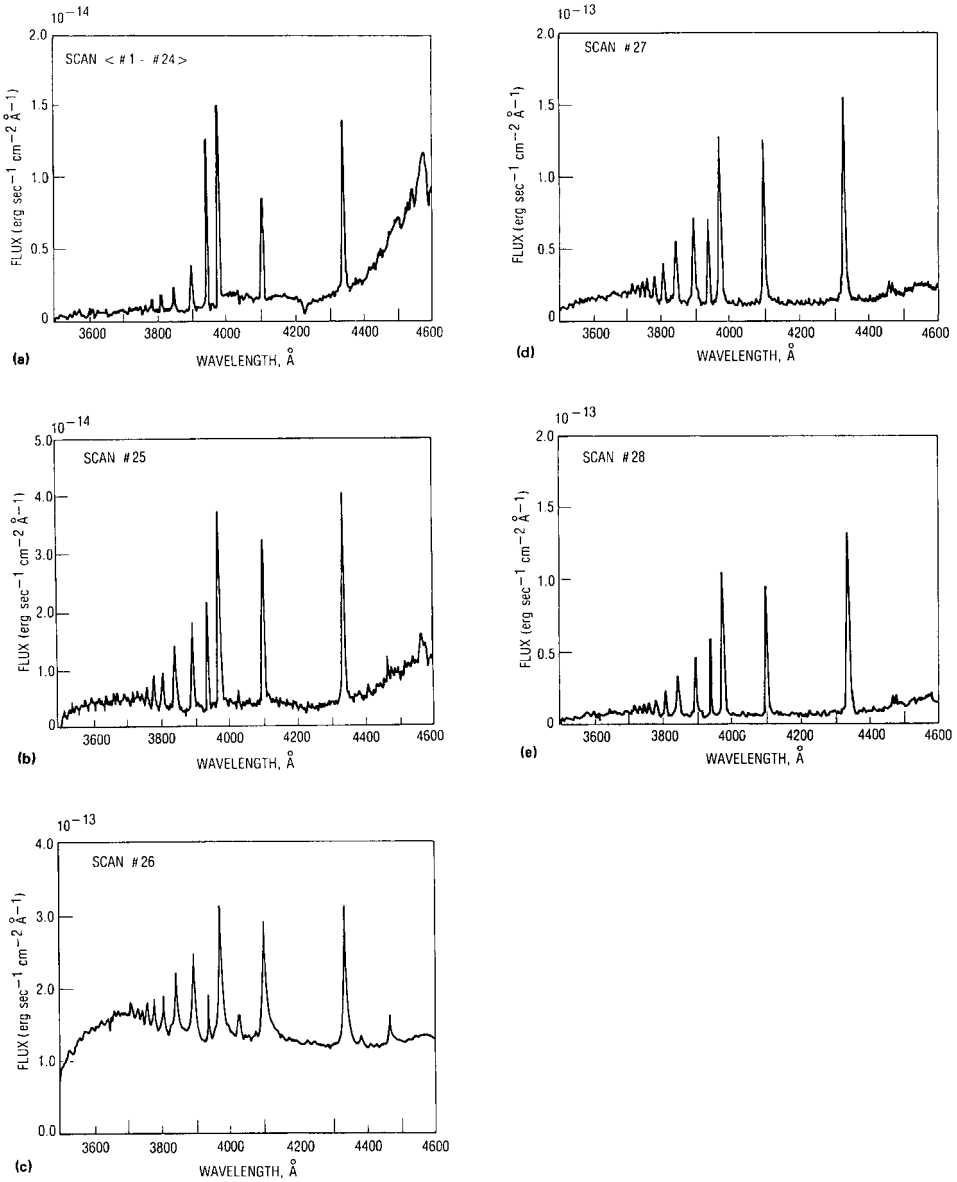

Figure 4. Spectrum of a large flare event. Time sequence of the blue spectrum of the flare star UV Ceti (dM5.6e) during the onset of a strong flare that exhibited a 5 mag increase in the photometric *U* band. The first scan is the average, quiescent spectrum of the star. The Ca II H and K lines are strong, and the Balmer series is evident out to H14, even during quiescence. The following scans document the onset of the flare event. Note the varying vertical axis scales. Emission lines from hydrogen are the most numerous and prominent emission features during the flare itself. Strong continuum emission is seen at the peak of the event in scan 26. Note the red asymmetry that appears in the emission lines at flare maximum, indicating the possible presence of mass motions. These spectra were originally obtained with the 2.3 m telescope and Reticon detector of the Steward Observatory of the University of Arizona. (From Eason E L E, Giampapa M S, Radick R R, Worden S P and Hege E K 1992 *Astron. J.* **104** 1161.)

disclosed the occurrence of an x-ray flare on the very-low-mass star VB 10 (dM8e). VB 10 is the latest-type, lowest-mass main-sequence star known to exhibit coronal activity. The peak luminosity of the flare was $\sim 10^{27}$ ergs s^{-1}. This is at least 2 orders of magnitude greater than the quiescent x-ray luminosity of VB 10, which has yet to be measured.

Concluding remarks

The manifestations of magnetic-field-related activity in the red dwarfs and flare stars are especially vivid because of the sharp contrast between the high-temperature emission features, arising from nonradiatively heated plasma at temperatures extending from $\sim 10^4$ to 10^7 K, against the cool photospheres with effective temperatures in the

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

~2500 K–4000 K range.

The origin of the surface magnetic field itself in the Sun and cool stars is ascribed to interior dynamo action involving the interaction between rotation, convection and extant magnetic fields. Empirically, coronal x-ray emission and chromospheric line emission strengths are correlated with rotation in red dwarfs. Magnetic field measurements by S Saar suggest an inverse relationship between rotation period and the area coverage, f, of magnetic flux of the form $f \sim P_{\rm rot}^{-1.8}$ for rotation periods greater than 3 days. At more rapid rotation periods, the surface is saturated with magnetic fields. However, the total magnetic flux, i.e. the product of the field strength and fractional area coverage, continues to increase with more rapid rotation rates according to the preliminary, empirical relation $fB \propto P_{\rm rot}^{-1.7}$. The implication is that magnetic field strengths continue to increase with increasing rotation rates, perhaps forming dark starspots.

In the Sun, the magnetic field that eventually appears on the surface in the form of plages, spots and flares is widely considered to have originated in an interface region between the outer convection zone and the interior radiative core. While this dynamo model may indeed apply to cooler dwarfs, it is the regime of the red dwarfs where the transition from a partial to a fully convective interior occurs. Thus, in the absence of an interface layer between the radiative and convective regions, another dynamo mechanism must then operate to continue to give rise to the variety of magnetic activity that persists into the wholly convective red dwarfs and flare stars. The nature of this new dynamo mechanism is a key question in current research efforts involving red dwarfs.

The physical mechanism that leads to the spectacular flare events in these cool stars is also unknown but is believed to involve, as in the Sun, magnetic reconnection. The energetics of stellar flares can often be accounted for within the context of two-ribbon flare models. Nevertheless, neither the actual flare morphology nor the true plasma-heating mechanism is known in the case of stellar flare events. Large stellar flares, like their solar counterparts, probably represent the superposition in space and time of many evolving flare regions in a flaring complex that could encompass a geometrically extended, large volume of emitting plasma.

Other key questions involving red dwarfs and flare stars include the possible contributions by these active objects to the diffuse galactic x-ray background, the evolutionary relationship between the active dMe flare stars and the relatively quiescent dM stars; whether red dwarfs exhibit cycles in their activity analogous to the solar cycle, the relationship of red dwarfs to brown dwarfs and the frequency of extrasolar planet formation among the low-mass stars. As always in astronomy, advances in instrumentation and analysis techniques will yield new insights on these common yet fascinating stars.

Red Giant Stars

Most stars are less massive and less luminous than the Sun, yet most of the visually bright stars are considerably more luminous than the Sun. Many of these are also cooler than the Sun, so that their higher luminosity indicates a much greater diameter, although they are not necessarily more massive. These are then known as giant stars, whereas the Sun is a dwarf. This difference in structure results from their being at different stages in their evolution (see STELLAR EVOLUTION). Dwarf stars derive their energy from hydrogen burning in the core, whereas giant stars have already exhausted hydrogen in the core, although they may still burn hydrogen in a surrounding shell, and may burn helium or even heavier elements in the core.

Stars are classified according to their surface temperature which dictates the degree of ionization and excitation of the atoms in the visible outer layers of the atmosphere. The main classes, from hot to cool, are denoted as O, B, A, F, G, K, M. Classes L and T have been added recently to describe very cool dwarf stars. There are also giant stars with peculiar surface composition. The R and N stars, which are sometimes lumped together as C, are carbon rich. The S stars are those in which the TiO molecule, which is the defining characteristic of the M-type spectra, is joined and ultimately superseded by ZrO and other molecules containing elements produced by the nuclear reaction known coincidentally as the s-process.

Giants and dwarfs may be distinguished by subtle spectroscopic differences, notably the greater strength of singly ionized metals in giants at any given temperature. The basic difference in luminosity is determined by trigonometric PARALLAXES which are based on observing the tiny angular movement relative to more distant stars which is produced by the Earth's annual motion relative to the Sun. The recent HIPPARCOS satellite measured the trigonometric parallaxes and hence distances of many stars to unprecedented accuracy. Giant and dwarf stars may also be present in a single cluster of stars all at the same distance, and then the difference in luminosity is observable directly.

Most of the giant stars which are visible to the naked eye or are seen in clusters such as the Hyades and Praesepe are of spectral type K and appear yellow to the eye. The true red giants are cooler, of spectral type M, S or N, and are much more luminous and represent the tip of the giant branch. They show a variety of interesting phenomena, including altered surface chemical composition, variability and mass loss.

The development of the technology for the efficient detection of infrared radiation has opened up a new field in recent years. Many red giant stars have been found to have extensive dust shells which, radiating at a temperature of a few hundred kelvin, are only detectable in the infrared. Some of these stars have such thick dust shells that the star itself is invisible at optical wavelengths, and the INFRARED ASTRONOMY SATELLITE (IRAS) which was equipped with a small infrared-sensitive telescope discovered thousands of stars whose existence was unknown to ground-based astronomers.

The giant branch

The recognition that the cooler stars are clearly divided into two groups, large bright giants and small faint dwarfs, was one of the principal results of the first large surveys of trigonometric parallaxes. This result is encapsulated in the HERTZSPRUNG–RUSSELL (HR) DIAGRAM, named for its independent discoverers, in which a measure of luminosity is plotted against a measure of temperature—originally spectral type but usually a photometric color—which increases to the left. Figure 1 shows

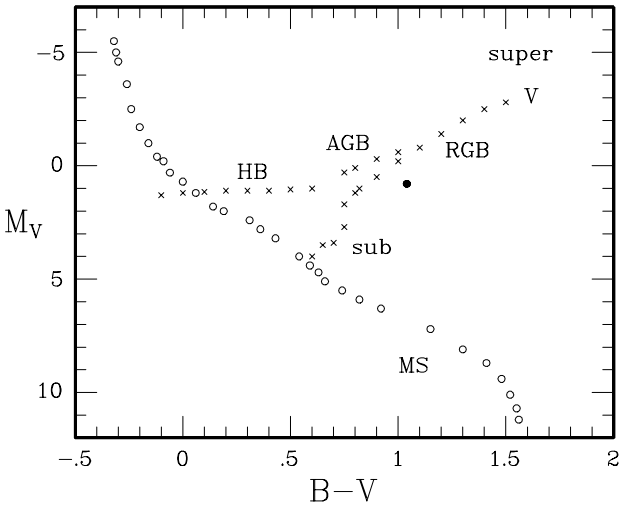

Figure 1. The HR diagram in the now usual color-magnitude form. The main sequence (MS) of H-burning dwarf stars slants from upper left to lower right (open circles). The subgiant branch (sub), red giant branch (RGB), horizontal branch (HB) and asymptotic giant branch (AGB) of a typical metal-deficient globular cluster are denoted by crosses. The AGB and RGB are only clearly separable at relatively low luminosity; it is a matter of inference that the most luminous red giants and especially those with altered surface composition belong to the AGB and not to the RGB. The V at the tip of the RGB–AGB indicates the position of red variable stars in the cluster. The filled circle to the right (red) of the RGB is the approximate position of the red giant clump in the more metal-rich stars of the solar neighborhood, while the RGB of this population lies just to the red of the clump (figure 2). Note that this diagram is based on the visible spectrum only and the hottest and coolest stars would appear relatively brighter if their entire luminous output, the bolometric luminosity, were considered. Conversely, the brightest stars of intermediate (solar) surface temperature fall above the upper limit of this diagram and the cool red variable stars of high metal content are visually much fainter than those in globular clusters denoted by V. The massive red supergiants of the younger population (super) fall in the top right of the diagram.

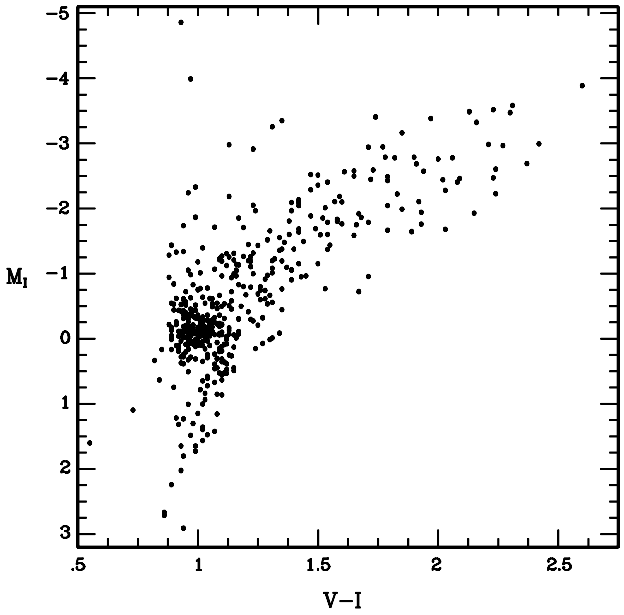

Figure 2. The color-magnitude diagram for nearby K and M0–M3 giants with well-determined parallaxes from the Hipparcos Catalog. The choice of *V-I* instead of the more usual *B–V* as abscissa uses TiO to expand the temperature scale for the cooler stars. The red giant clump is prominent near *M*I=0, *V–I*=1.0, and the red giant and asymptotic giant branches run together to higher luminosity (i.e. upward) and lower surface temperature (to the right). The few stars which lie above this are probably more massive stars. The RGB and AGB are not separable in this mixed population of stars from the solar neighborhood.

a composite color-magnitude diagram for dwarf stars near the Sun and giant stars in a typical GLOBULAR CLUSTER, using representative points along the corresponding sequences. This figure illustrates the terminology we introduce in this section and use throughout the article. It follows from the difference in luminosity that the coolest giants shown have radii which are several hundred times those of dwarfs of similar effective temperature.

Dynamical studies of BINARY SYSTEMS show that a typical giant star has a mass in the range 1–3 times that of the Sun so that the difference in radii between giants and dwarfs results from a difference in structure rather than of mass. The mean density of the Sun is close to that of water but that of a giant star may be more than a million times less. This matter is not evenly distributed, however, because while the Sun has a ratio of the central to the mean density of about 50:1 the corresponding figure for a giant can be as large as 10^8:1. The giant has a very small dense energy-generating core which contains over 10% of the mass of the star.

Observations of stars in clusters, which have the great advantage that all the stars lie at almost the same distance, so that their apparent luminosity gives their true relative luminosity, and usually have the same age and chemical composition, revealed the detailed structure of the giant branch. There is a marked concentration of stars at a luminosity about 40 times that of the Sun and slightly to the blue (hot) side of the red giant branch (RGB). This takes the form of a compact clump, the red giant clump, in open star clusters of high metal content and in the stars of the solar neighbourhood.

The red giant clump, whose location is marked in figure 1, is shown in more detail in figure 2. Figure 2 shows the color-magnitude diagram for a sample of nearby stars, based on high-quality trigonometric parallaxes obtained with the Hipparcos satellite. The early K stars are strongly concentrated in the red giant clump, while cooler K and early M stars extend to redder colors and higher luminosity; the intrinsically fainter stars are under-represented because star selection is by apparent magnitude. The clump becomes the horizontal branch, extending to much higher surface temperature, in the old metal-deficient globular clusters. The luminosity of the clump is very similar to that of the horizontal branch, as is well seen in the HR diagrams of nearby galaxies where both populations are present. The extension of the clump to the upper left in figure 2 represents stars which are substantially more massive then the majority.

The originally single giant branch becomes double at higher luminosities than that of the clump. This is not apparent in figure 2, where observational error and the range of mass and chemical composition among the nearby stars obscure the finer details. Observations of globular clusters showed that the giant branch extends as a sharp continuous locus from the subgiant branch which follows from the main sequence turnoff to the tip at a luminosity about 1000 times brighter. This is joined by a second giant branch which starts above the horizontal branch, displaced to the hot (blue) side of the RGB, and runs progressively closer to the RGB until they become indistinguishable. This second giant branch is known as the asymptotic giant branch or AGB. This is shown in figure 1 and in more detail for the giant stars in the moderately metal-poor globular cluster 47 Tucanae in figure 3.

Theoretical calculations have been able to reproduce these main features of the observed HR diagrams with some precision, yet the fundamental reason for the change in structure from the dwarf to the giant state has been hard to establish. Recent work shows that the expansion of the envelope following increasing luminosity in the core causes cooling, ion recombination and an increase in the opacity of the envelope. The inability of the envelope to transmit all the luminosity impinging on its base causes further expansion which exacerbates the situation, leading to a runaway expansion which only stops when the entire envelope becomes convective and energy can be transmitted to the surface by this more efficient process. The locus of a convective envelope in the

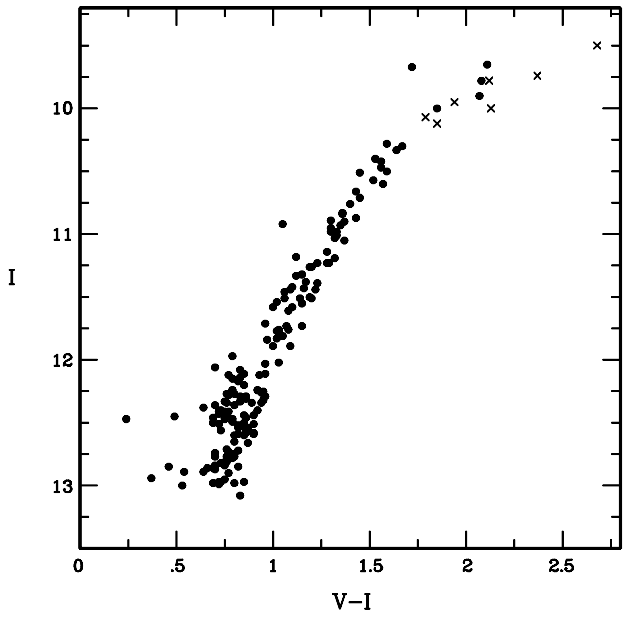

Figure 3. The color-magnitude diagram of the moderately metal-poor globular cluster 47 Tucanae. The short red horizontal branch lies below the limit of this figure, near *I*=13.4. Note the clump on the AGB for *I*=12.0–12.4, with gaps both above and below, with a resumption near *I*=11.8. The crosses denote semi-regular variable stars. This old and moderately metal-deficient cluster has a much steeper giant branch than the younger, metal-rich stars in the solar vicinity (figure 1).

HR diagram, the Hayashi track, defines the position of the giant branch.

A star leaves the main sequence and moves to the red on the subgiant branch when it has exhausted hydrogen in its core; hydrogen burning continues in a shell surrounding the currently inert helium core. This energy-generating shell gradually moves outwards, consuming hydrogen from the pristine outer layers and depositing helium and other reaction products on the core. The core in a star with a mass of not more than about two solar masses is degenerate during the ascent of the giant branch. The term red giant branch (RGB) is sometimes used specifically to refer to this stage in the evolution of a low mass star, although it is not easy to distinguish observationally between such stars and stars in the next (AGB) stage of evolution or more massive stars without degenerate cores. The H-burning shell moves outwards and at some stage it encounters the inner edge of the relatively H-rich convective envelope: the ascent of the giant branch slows for a time, causing a concentration of stars at this point on the giant branch. This is well seen in rich star clusters and is known as the RGB bump. The spectra of stars higher up the giant branch show a decline in the carbon isotope ratio; this is consistent with the mixing of an increasing quantity of the products of the CNO cycle of H-burning into the envelope. Observations of star clusters show that this process, which is not yet fully accounted for by theory, is most pronounced in metal poor stars of low mass.

The ascent of the RGB continues until ignition of the triple-alpha process of helium burning in the core. The reaction rate builds up very rapidly because of the strong temperature dependence of the nuclear reaction coupled with the inability of the degenerate material to expand and cool in response to the energy input. The degeneracy is lifted eventually and helium burning stabilizes. The rate of energy production in the star is considerably reduced during this stage, so the process described in the previous paragraph occurs in reverse and the star moves rapidly down the Hayashi track until equilibrium returns at the red giant clump or its equivalent. The theory requires mass loss to occur after the ignition of helium in the core. This is especially the case for the bluer HORIZONTAL BRANCH STARS which can only have a very small mass in the envelope. No direct evidence has been found for this mass loss so far. The process is so rapid that we would not expect to observe many stars in transit.

A star of more than about two solar masses does not have a degenerate core. The star does not increase greatly in luminosity on the giant branch before helium ignites in the core and the surface temperature increases; it spends most of its core helium burning life in a band to the blue of the giant branch. Observations of star clusters of a range of ages show the red giant clump in the oldest clusters becoming brighter and bluer as successively younger clusters are considered. These younger clusters lack the tall giant branch (RGB) of the older star clusters.

The asymptotic giant branch

The second ascent of the giant branch follows the exhaustion of helium in the core. The star now consumes hydrogen and helium in concentric shells. Instabilities occur in the energy-generating shells at high luminosity. Thermal pulses in the helium-burning shell may cause the temporary extinction of the hydrogen-burning shell, with substantial changes in the total energy production of the star and in its structure and luminosity. The observational consequences of this include changes in luminosity and in the character of the variability which is a general feature of such luminous red giant stars. This would most easily be seen by comparison with other stars in a cluster, but this evolutionary stage is quite short and well-populated clusters of the relevant age are few, so this effect is hard to establish.

These disturbances to the structure of the star lead to additional nuclear reactions as a result of material from the region outside the reaction zone being drawn into it. Deep convection in the envelope then brings reaction products to the surface of the star. This is known as the third dredge-up mechanism, as there have been earlier convective upwellings of processed material. The princi-

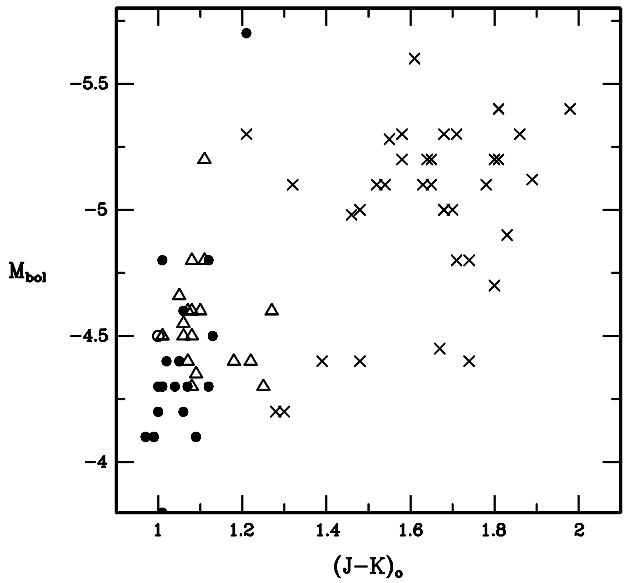

Figure 4. The composite near-infrared color-magnitude diagram of the upper asymptotic giant branch in star clusters of intermediate age in the Magellanic Clouds. Filled circles are early M stars, the open circle is a K star, the open triangles are MS or S stars and the crosses are carbon stars. The transition from M via S to carbon stars is clear.

pal reaction products brought to the surface are carbon, mainly the ^{12}C isotope produced by the triple-alpha process of helium burning, and heavy elements made by the slow neutron process (s-process).

The addition of large quantities of these materials to the STELLAR ATMOSPHERE causes spectacular changes to the spectral appearance, as these stars are cool enough to have spectra dominated by molecules and the principal molecules present depend on the chemical composition of the atmosphere.

The very low surface gravity and high luminosity of these stars are conducive to mass loss from the stellar atmosphere; this is observed and may occur at a high rate. Loss of the stellar envelope is the penultimate stage before the appearance of a WHITE DWARF star as the endpoint of the evolution of a star of small or intermediate mass; a more massive star will end its giant stage of evolution in a SUPERNOVA explosion. The ejected material from a low-mass star appears for a while as a PLANETARY NEBULA in which the material is ionized by the hot stellar remnant. The thermally pulsing AGB (TP–AGB) stage of evolution is thus one of the most dramatic in the whole evolution of a star.

The changing chemical composition of the atmosphere

Carbon produced by the triple-alpha reaction may change the normally oxygen-rich atmosphere to one in which carbon is more abundant. Most oxygen and carbon atoms are tied up in the CO molecule at the low photospheric temperature of these stars, so that only the more numerous species is available in quantity to form other molecules. Thus the spectra of the oxygen-rich M stars are dominated by oxygen-bearing molecules such as TiO and VO, while C_2, CH and CN are prominent in the spectra of the carbon-rich N stars. Stars with C/O very close to unity do not have strong bands of carbon- or oxygen-bearing molecules, although unusual molecules such as CaCl may be present; these stars are called SC or CS stars depending on whether they are marginally O or C rich. (Figure 5 shows examples of the spectra of cool giant stars of different surface composition.)

Nuclei produced in the STELLAR INTERIOR by the s-process are brought to the surface at an early stage and their presence is recorded by the appearance of ZrO, YO and LaO in oxygen-rich stars. These are classified as S stars if the additional bands are comparable with or stronger than TiO, or MS stars if these bands are weak. The lines of the s-process elements are also enhanced in the spectra of most CARBON STARS. Conclusive proof that this material is produced by an ongoing process in the star itself is provided by the presence of lines of Tc. This

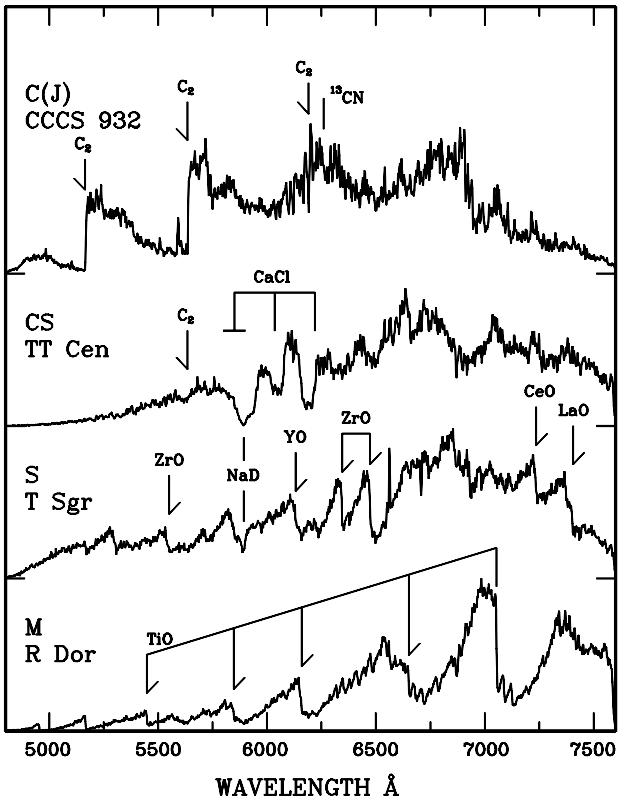

Figure 5. Optical spectra of M, S, CS and C type in the yellow-red spectral region. These show the very different sets of molecular bands which characterize these stars. These stars, except for the carbon star which is of the ^{13}C-rich J subtype, are rather cool examples or, as for TT Cen, were observed when the bands were strong. The original spectra were taken with an intensified Reticon detector at a resolution of 5 Å.

is an s-process element with a radioactive half life of only 2×10^5 yr so that no significant quantity would remain from the time when the star was formed.

The evolutionary sequence M to S to N was proposed on theoretical grounds and ultimately proved by observations of stars of these types at successively higher luminosities on the upper giant branch of star clusters in the MAGELLANIC CLOUDS (figure 4). These clusters have ages of typically 10^9 yr and the giant stars have a mass of about 2 solar masses. Stars of type S and N are not found in the old globular clusters with evolving stars of a solar mass or less. Figure 5 illustrates the dramatic difference in spectroscopic appearance which results from the changing abundances of carbon and the s-process elements. The stars shown are galactic field stars which were selected as extreme examples with strong bands and do not represent an actual evolutionary sequence such as is seen in the Magellanic Cloud star clusters.

The spectra of M stars can be classified in terms of parameters which correlate well with surface gravity, which gives an indication of luminosity, and the photospheric temperature. This is not so for the cooler or N-type carbon stars, although the hotter R-type carbon stars are more tractable. The Na D lines seemed to offer a temperature criterion for the N stars, but the C/O ratio has a great influence on these and other resonance lines. The features which work well as luminosity criteria in ordinary giants and dwarfs, notably the Sr II lines and CN bands, are affected by the s-process and carbon enrichment and cannot be used. The CN strength also depends on the N abundance which, unlike the C abundance in the carbon stars, is essentially that with which the star was formed. Thus carbon stars in the Magellanic Clouds, which are N deficient, have weaker CN bands than most galactic carbon stars. The few galactic N stars with weak CN bands have the high space velocity typical of the old, metal-deficient stars of the galactic halo.

The transition from M to S to N occurs at a spectral type of about M4 in the Magellanic Cloud clusters. The stars near the transition are either constant in light or at most show small variations; these clusters contain a few much redder stars which are the mass-losing stars at the tip of the AGB. Thus the transition occurs well below the tip of the AGB in these moderately metal-deficient stars of two solar masses. The transition may occur at different points in different systems, for instance there are no N stars in the Central Bulge of the Galaxy although O-rich M stars are very common.

The Central Bulge of our Galaxy contains a very metal-rich old population. The quantity of carbon which must be dredged up to produce a carbon star depends on the relative quantities of oxygen and carbon which are present to start with, and it will be less if there is relatively little oxygen as in the case of a metal-deficient star. The trend of an increasing proportion of carbon stars in the sense galactic center, solar neighborhood, LMC, SMC may be dictated primarily by the metal content which decreases in this sense. It may be affected also by the distribution of stellar masses, which in turn depends on the history of star formation in each system.

There are also red giants of unusual surface composition which cannot have arisen in this way, mainly because the luminosity is far below that at which the third dredge-up occurs. The CH STARS AND BARIUM STARS, which are hotter and fainter than the stars described above, and some S stars which lack Tc lines so that their s-process material may be ancient, are found to be members of binary systems. The companions, when detected, are white dwarfs. This suggests that the companion was initially of higher mass and has already passed through the red giant stage. The processed material which gives the characteristic spectrum of the star now in the giant stage may therefore be attributed to reactions within the formerly more massive companion. This material would have been transferred when the original primary reached the mass-losing stage, or perhaps earlier if it overfilled its ROCHE LOBE as soon as processed material reached the surface layers. The existence of subdwarf and even dwarf CH and carbon stars is most easily understood in this way.

The R stars are the hotter carbon stars and are an inhomogeneous group. They include CH stars and the hydrogen-deficient carbon stars. The latter include the R Coronae Borealis stars, which undergo deep visual fading when clouds of soot are ejected. The carbon is almost pure ^{12}C and it is thought that these stars represent the final 'reborn' giant phase of the carbon core produced by the triple-alpha process of helium burning; as such they fall off the main line of evolution described above. Many of the remaining R stars form a group difficult to understand. There are unusually few binary stars among them while the spectra are characterized by a low $^{12}C/^{13}C$ ratio, suggesting that the carbon has been processed through the CNO cycle in a hydrogen-burning zone, and by the absence of an enhancement of the s-process elements. One possibility is that the helium core flash at the top of the RGB took an unusual course so that the products of hydrogen-burning were dredged up in quantity. The star would then be a carbon star at the red giant clump and throughout its ascent of the AGB. Theoretical calculations cast doubt on this: they indicate that only stars of exceptionally low metal content can become carbon stars in this way—such carbon stars have been discovered recently.

Some of the cooler N stars also have a low $^{12}C/^{13}C$ ratio: these are often called J stars. These amount to only about 15% of the local N star population, so it is surprising that many of the CH stars in both globular clusters and the field exhibit this property, which might suggest that the donor stars were not typical of carbon stars in

general. It has been proposed instead that the process of mass transfer caused deep convection in the stellar envelope of the receiving star, so that some of the material in the envelope has been processed by the CNO cycle in the H-burning shell.

Variability and mass loss

The coolest and most luminous stars are intrinsic VARIABLE STARS. The variability is usually at least quasi-periodic, with periods of a few hundred days in the case of the stars of larger amplitude. These are the long-period variables, divided into semiregular and MIRA VARIABLES. The latter are conventionally defined by having visual amplitudes greater than 2.5mag. They are also more regular and have longer periods. The visual amplitudes may be as great as 10 magnitudes in the case of some M and S stars. The TiO bands become very strong when the star is coolest and depress the luminosity in the *V* band, so that the amplitude is much greater than it would be in a star without absorption bands. The corresponding amplitudes at 2 μm are only 1–2 mag. The carbon stars do not have such strong molecular bands in the *V* band and generally have much smaller amplitudes in visual light.

A few stars have shown large abrupt changes in period and amplitude, indicating changes in the mode of pulsation, and the precise MACHO photometry of a large sample of stars in the Magellanic Clouds shows that several pulsation modes are possible and that more than one may be active at the same time in a given star. Several relationships between period and other properties are known. The longer-period stars have lower space velocities and so belong to a younger population, while among those in globular clusters the most metal-rich clusters have the stars of longer period. None is known in very metal-deficient clusters. The central bulge of the Galaxy, where the metal abundance is high, has relatively more Miras of very long period (around 500 days) than the solar neighborhood.

Infrared studies have revealed large quantities of dust around many of the most luminous giant stars. Most Mira variables and many semiregulars show emission from dust at 12 μm the Miras are systematically brighter at this wavelength relative to the photospheric emission at 2 μm. The few Miras in globular clusters have comparatively little circumstellar dust, which is made of the heavier elements which are deficient in globular cluster stars. The Miras of longer period all have dust shells. The most extreme cases, Miras of very long period, are invisible in the optical region because of the great extinction by the dust. The O-rich stars among them usually have strong OH maser emission in the microwave region and are known as OH/IR stars because they are observable only at these longer wavelengths. Many visible Miras and some semiregulars show weaker OH emission.

Maser emission from SiO and H_2O is also sometimes observed, but from different radial regions. SiO emission arises relatively near the photosphere and OH from very far out in the shell, while H_2O is located at an intermediate radius. The microwave emission in the form of sharp lines allows the measurement of radial velocities and it is found that the material is generally in the form of a shell with an expansion velocity of up to a few tens of kilometers per second. The combination of the expansion velocity with an estimate of the size of the shell and the density of the material allows the rate of mass loss to be estimated. The mass loss becomes observable at a rate of about 10^{-7} solar masses per year, and reaches 10^{-4} solar masses per year in the most extreme cases. This stage of evolution is necessarily shortlived, as is also apparent from the scarcity of such stars.

The dust emission has its own characteristic spectrum, dominated by silicate emission bands at 9.7 and 18 μm in the O-rich stars and by SiC emission at 11.4 μm in the carbon stars. The OH/IR stars show silicate absorption features but SiC is rarely seen in absorption in heavily obscured carbon stars. Carbon-based dust grains absorb more heavily in the optical region than does the silicate material around the oxygen-rich stars, so that a higher proportion of carbon stars are optically invisible. Many have only recently been found by infrared studies and it appears that the carbon Miras which are known from optical searches are only the less-obscured tail of a much larger population.

The ejection of material from the red giant stars is unlikely to occur at a constant rate. Long-continued observations of carbon-rich Miras show that the mean brightness varies on a time scale of decades (figure 6).

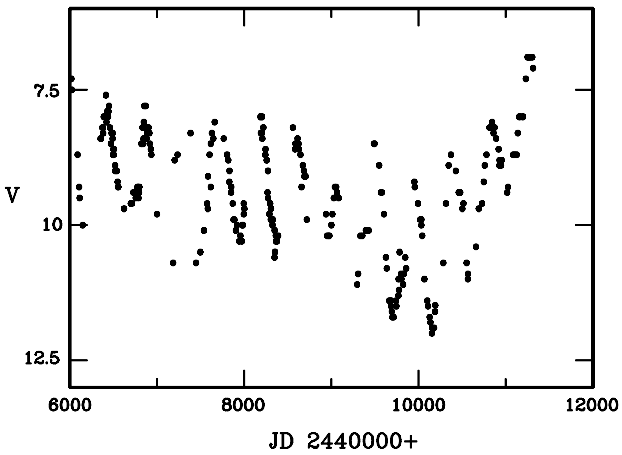

Figure 6. The light curve of the carbon Mira, R Lep, from visual observations by amateur astronomers in South Africa. The appearance of the resonance lines of Na, K and Rb and the C_2 bands in emission coincided with the marked fading of the overall light curve near JD 2 450 000 when two successive minima were exceptionally faint. These emission features disappeared rapidly when the star brightened up again. The last maximum shown is the brightest for many years.

These stars are much redder during their faint episodes in a manner consistent with increased extinction by dust. The visible light spectrum is normally dominated by absorption bands of C_2 but during a faint episode these bands appear in emission instead; the resonance lines of Na, K and Rb appear in emission at the same time. This is suggestive of resonance fluorescence emission; the geometry remains to be established.

Hubble Space Telescope pictures of some stars with bright circumstellar material show many apparently concentric shells which suggests that mass loss has been episodic. The time scale is probably that of the helium shell instability which must cause major re-organization of the envelope and so disrupt the mass loss process.

Recent studies in which stars were selected by the IRAS and ISO infrared satellites for their far-infrared emission have revealed M stars with as much circumstellar material as the Mira variables but which are not conspicuously variable. These could be stars which alternate between Mira and small-amplitude pulsations, the dense shell being produced during the Mira episodes. The situation may alternatively imply that pulsation of large amplitude is not the only way to initiate large-scale mass loss. The flat energy distribution of some stars which are not variables of large amplitude but which have excess emission at both 3 μm and 60 μm relative to a typical Mira, may indicate that the circumstellar material is in a disk. The most extreme examples of stars with this type of energy distribution, which is not confined to very cool stars, sometimes show emission of the resonance lines of Na, K and Rb. This may be understood by a model, first put forward for the M star VY CMa, in which the star is hidden by an edge-on dust disk and is visible only by reflection from circumstellar material out of the plane of the disk. The resonance emission arises in this material.

The J-silicate carbon stars are an enigmatic group which combine the photospheric spectra of carbon stars with the circumstellar material normally associated with oxygen-rich stars. The J notation refers to the enhancement of ^{13}C in the spectra of most members of this group. These stars have a large value of the IRAS [12]–[25] index, in the range 0.8–1.8. Normal optically visible carbon stars nearly all have [12]–[25] <0.6 and redder objects are hidden by their circumstellar dust. OH and H_2O emission is seen in some cases, in agreement with the inference that the circumstellar material is O rich. The velocity structure suggests that the material is in a disk, and this is supported by the excess emission in the near infrared (around 3 μm) which is measured in some cases. A disk is a much longer-lived structure than an expanding shell and it is possible that O-rich material ejected in the previous evolution of the star, before it became a carbon star, has been retained in this way. The existence of a disk, formed from ejected material, around a single star is not easy to understand, but would be facilitated if the star is in a binary system. No direct evidence for the presence of companions has been forthcoming. Dusty disks of this type seem to be peculiar to J-type carbon stars, as similar near infrared excesses have not been found in ordinary N stars, although they are known in some M-type stars.

Giant stars in binary systems

Giant stars are not found in short-period binary systems because they would not fit. A star in a binary may evolve normally until it expands to fill its Roche lobe, following which further expansion will lead to rapid mass loss to the companion. The minimum separation of a binary system is thus such that neither star has filled its Roche lobe during its evolution to date. The present stellar radius may be much less than the maximum in the past. A classical Cepheid, a star with typically five times the mass of the Sun and in the core-helium-burning stage of evolution, would fit into a system with an orbital period of about 40 days, but the shortest periods known for binary systems containing Cepheids are about 500 days. This reflects the radius of the Cepheid when it was at the tip of the first ascent of the giant branch. Similarly, the minimum binary separation which will accommodate a star of the red giant clump is that which would accommodate the star when it was at the tip of the RGB.

Giant stars in binary systems may show evidence of interaction in the past, even though there has not been overflow of the Roche lobe. The orbits of the systems with the shortest orbital periods, with one component which is close to filling its Roche lobe, are invariably circular. A mean separation in excess of that of the smallest possible circular orbit is required to accommodate the giant star if that the minimum separation of an orbit is eccentric, as there must be space for the giant star when the stars are closest together. Tidal interaction works to reduce the eccentricity.

K giants which are members of binary systems with orbital periods less than about 100 days often show enhanced chromospheric activity, resulting in strong emission reversals of the Ca II H and K lines. Many show light variations caused by large starspots which move across the line of sight as the star rotates, so the light of the star is modulated at the rotational period of the star. There is normally close synchronism between the period of rotation of the giant star and the orbital period of the binary system. This is also a consequence of tidal interaction between the components.

The binaries where the separation is such that the evolving (giant) star will fill the Roche lobe set by the gravitational field of its companion undergo mass exchange from the evolving star to its companion. Mass loss from the system is also likely, in which case the size of the orbit will be affected. Gas in the system, whether in transit from one star to the other or in a ring or disk around one of the stars, may contribute atomic emission

lines to the spectrum of the system. The evolving star generally loses so much mass that it is stripped down and becomes the fainter of the pair, although it still has a large radius. This is the type of system which, seen edge-on, will undergo Algol-type eclipses. The now-fainter star is difficult to study without interference from the companion, but analyses of the light from the photospheres and coronae of several stars have shown that the chemical composition has been altered by the dredging-up of nuclear reaction products to the surface. There is increasing interest in the idea that some of the chemically-peculiar stars may owe their nature to such extreme interactions with companions which, unlike in the case of the Algol systems, are too faint to be obvious in the combined light of the system.

SYMBIOTIC STARS and some NOVAE in which the mass donating, non-degenerate component is a giant belong to the class of cataclysmic variables. The strong stellar wind of the giant may suffice to drive such activity even if the giant star does not overflow its Roche lobe. The type star of the Mira variables, Mira Ceti is a marginal example of this type. It has a companion star, at a distance of a few arcseconds, which has H emission lines and is variable. It shows both erratic rapid variability, caused by variable accretion, and long-term variability, which may result from changes in an accretion disk. These phenomena are best seen in the ultraviolet spectral region, to which the red giant contributes little.

More massive giant binaries, in which mass interchange has not yet had major evolutionary consequences, may be detected by their composite colours and spectra when the companion is a dwarf of type A or B and comparable in luminosity with the giant. Some of these systems have nearly edge-on orbits so that the small hot star acts as a probe of the atmosphere of the giant star when it passes behind it. Lines arising in the atmosphere or extended atmosphere of the giant are seen projected on the featureless spectrum of the hot star. Velocities and densities in the atmosphere of the giant star may be studied in this way. Dense clumps of gas have been found in the extended atmospheres of K supergiant stars in binaries by this means.

Stars in globular clusters

The globular clusters in our Galaxy show a wide range in chemical composition. The ratio Fe/H ranges from a value not far below solar to over 100 times less. The sharpness of the giant branch and the good agreement of the results of spectroscopic abundance analyses of the individual stars indicate that there is little spread in the iron abundance within a cluster, with the notable exception of Omega Centauri and possibly also M22. There is a relatively small range in age, of perhaps two billion years compared to an average age of over ten billion years, among the globular clusters in our Galaxy. The globular clusters were the first clusters to be formed in the Galaxy and nothing similar appears to have been formed in our Galaxy since, although some nearby galaxies contain rich young clusters.

The much smaller numbers of stars in the younger open clusters do not suffice to study the giant branch in such detail, although the populous young and intermediate-age clusters in the Magellanic Clouds as well as the DWARF SPHEROIDAL GALAXIES which appear to have a simple star formation history help to fill in the gaps. The globular clusters allow the location of the giant branch, sometimes known as the Hayashi track, to be studied as a function of chemical composition at constant age. The giant branch is displaced to the red in the color-magnitude diagrams for clusters of higher metal content and this has been calibrated spectroscopically, so that the metal content of more distant systems can be estimated from photometric data alone. Theory and observation show that mass differences have a much smaller effect on the colour of the RGB. The low mass and reduced metal content of the evolving stars in globular clusters preclude many of the phenomena we see in stars of the solar neighborhood. There are no long period Miras, no stars with thick dust shells and no carbon or S stars on the thermally pulsing asymptotic giant branch. The CH stars in several clusters are evidence that these phenomena occurred in more massive stars earlier in the life of the cluster.

The giant globular cluster Omega Centauri has long been known for having a broad giant branch, which is attributable to a range of metal content in the cluster. It has been shown recently to have stars of a range of age as well, and this has lead to the suggestion that it may be the remnant of a small galaxy cannibalised by the Milky Way. The chemical composition deviates from those found in other clusters as well as in the Galaxy at large, in that the stars of higher metal content show an exceptionally high ratio of the s-process elements to the iron group. The coolest stars show strong bands of ZrO and are classified as S stars. They are too faint to owe their overabundance of s-process elements to the operation of the third dredge-up themselves, and have presumably formed with this unusual composition as the result of incorporating material ejected by an earlier generation of more massive AGB stars.

The more metal-rich clusters such as 47 Tuc have short stubby horizontal branches, close to the giant branch, while the metal-deficient clusters have more extended or even predominantly blue horizontal branches. The discovery of clusters with red horizontal branches far out in the galactic halo suggested that, contrary to expectation, these clusters were relatively metal rich. It was soon found that the form of the horizontal branch is not solely a function of metal content and that a second parameter is involved. Age appeared as a likely contender for the second parameter but age determinations

from photometry of main sequence stars show that the age range among globular clusters cannot account for this. The clusters with red horizontal branches, other than those of relatively high metal content, are generally small or have a low central concentration. Stars on the blue horizontal branch are thought to have lost much of the mass of their envelopes, so it has been suggested that blue horizontal branch stars could have suffered stripping of the envelope by close stellar interaction in a densely crowded environment.

Massive stars

Much of our discussion so far has related to giant stars of low mass, typically less than about two solar masses on the RGB. Stars of higher mass differ in a number of ways. The red giant clump becomes brighter and somewhat bluer and the stage of core helium burning is now known as the blue loop. The loop extends to higher surface temperature for stars of higher mass or lower metal content. A star may pulsate as a Cepheid when it passes through the instability strip which lies well to the blue of the giant branch, and classical Cepheids, with masses between 3 and 9 solar masses, will be most common when the long-lived core-helium-burning stage falls within the instability strip. Subsequently the star will return to the giant branch. Observations of Magellanic Cloud stars suggest that stars of mass up to about 7 times that of the Sun pass through the AGB stage as described above, although the more massive stars do not become carbon stars.

Stars with moderate S characteristics (MS stars) are prominent among the most luminous identifiable AGB stars in the Magellanic Clouds. This is probably because increased CNO cycling converts carbon into nitrogen, so that there could in principle be nitrogen stars which, as C/O would be less than unity, would not be readily distinguishable from M stars. It is also possible that severe mass loss sets in to terminate evolution on the AGB before the C/O ratio exceeds unity, while the massive envelope of a star of high mass requires more processed material than that of a low-mass star to change its composition.

The mass range of these stars, 3–7 solar masses, implies that mid to late B-type main sequence stars and Cepheid variables may evolve into carbon stars or Mira variables but to date there is little direct evidence for this from the LARGE MAGELLANIC CLOUD clusters. The clusters containing carbon stars all have evolving stars within a relatively small mass range, 1.5–2.5 solar masses, but this appears to be limited on both sides by the age limits of a burst of star formation in the Large Magellanic Cloud. The failure to find carbon stars in clusters with B type main sequence stars and classical Cepheids may simply reflect a lack of large clusters of the correct age group.

Stars of still higher mass do not pass through the same evolutionary stages. Stars of mass around 10–15 times the mass of the Sun become M supergiants with luminosity class Ia, Ib or II rather than the luminosity class III giants of the lower mass stars. The Hertzsprung gap between the main sequence and the giant branch stars widens with increasing luminosity and there are few red supergiants of type earlier than M0. They are rarely of spectral type later than M3, that is they do not become as cool as the giants, and variables of large amplitude are almost unknown. One of the few exceptions is S Per, of spectral type M4–5 and with an amplitude which can reach 5 mag at times. These stars are found in several young star clusters in the Galaxy, with a concentration in the association around the Perseus Double Cluster.

The M supergiants have extensive circumstellar dust. The theoretical evolutionary tracks are nearly horizontal in the HR diagram plotted with luminosity or bolometric magnitude as ordinate. There is a loop to the blue after a red supergiant stage, then perhaps a second spell as a red supergiant before the star evolves to the blue again. The great width of the Hertzsprung gap implies very rapid evolution across the HR diagram, so that the evolved stars spend almost all their time as blue (spectral type B) or red (M) supergiants and move quickly through the intervening yellow supergiant stage. Supergiants of the intervening types, A, F, G and K, are known but are rare.

Bibliography

There is an enormous literature on red giants but several excellent reviews cover major parts of the topic. The *Annual Review of Astronomy and Astrophysics* is an excellent source and several recent reviews may be cited

Redshift

The redshift (or blueshift) of an object is the displacement of its spectral features to longer (or shorter) wavelengths due to a combination of the gravitational redshift, Doppler motions and the general expansion of the Universe. More properly, the term RADIAL VELOCITY is used primarily for the Doppler motions, which are usually the result of gravitational interactions, while redshift is reserved for the cosmological and direct gravitational effects. Redshift, z, is defined in wavelength as

$$z = \frac{\lambda_0 - \lambda_e}{\lambda_e} = \frac{\lambda_0}{\lambda_e} - 1$$

where the subscripts 0 and e refer to observed and emitted. In the frequency domain, redshift is defined as

$$z = \frac{\nu_e - \nu_0}{\nu_0} = \frac{\nu_e}{\nu_0} - 1$$

The dichotomy between these formulae is due to the fact that redshift causes wavelengths to increase and frequencies to decrease.

The redshift any given object can be decomposed as

$$z_{\rm total} = z_{\rm grav} + z_{\rm physical} + z_{\rm H}$$

where $z_{\rm H}$ is the cosmological redshift due to Hubble expansion and $z_{\rm physical}$ is the redshift due to the physical motion of the object with respect to the observer. In an expanding universe, the cosmological redshift is always positive (objects are always redshifted). The gravitational redshift as observed from the Earth is also generally always positive, but the physical motions of stars or galaxies can produce both redshifts and blueshifts, depending on whether the induced motion is away from or towards the observer respectively.

The gravitational redshift is due to the loss of energy light suffers when leaving a deep gravitational potential. Indeed, if the potential is strong enough, light cannot escape, the gravitational redshift is infinite and and a BLACK HOLE results. The gravitational redshift of a photon emitted at radius r_1 and observed at radius r_2 from a central mass is given by

$$\frac{\Delta\nu}{\nu} = \frac{-GM}{c^2}\left(\frac{1}{r_1} - \frac{1}{r_2}\right).$$

Gravitational redshifts have been measured in the Sun (see e.g. SOLAR PHOTOSPHERE: THE LIMB EFFECT AND GRAVITATIONAL REDSHIFT) and in only a small number of dense stellar objects such as WHITE DWARF stars. For example, the gravitational redshift of light leaving the surface of the white dwarf star Sirius B and viewed at infinity (or the Earth!) is about 0.000 06 or, in velocity units, $cz \sim 19$ km s^{-1}. The gravitational redshift of light leaving the surface of the Sun, which is much less dense than Sirus B and so has a much smaller gravitational potential well, is about 0.000 002, or only 0.6 km s^{-1}.

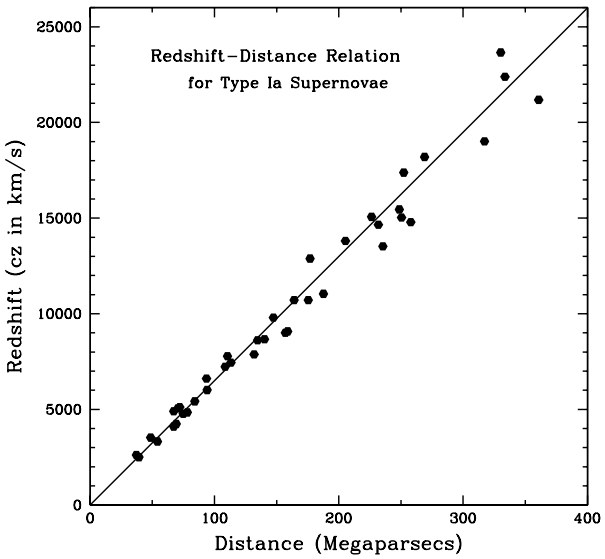

Figure 1. The redshift–distance relation for type Ia supernovae from the Calan-Tololo supernova survey (from data courtesy of S Jha, Harvard-Smithsonian). Redshift is given as cz and the distance is in megaparsecs (1 Mpc is approximately 3.26 million light years). The line through the data represents a Hubble constant of 65 km s^{-1} Mpc^{-1}, close to the value astronomers measure today.

Physical motions are most often gravitational in nature, such as the orbital motion of the Earth around the Sun. The Earth is in a nearly circular orbit around the Sun at a velocity of $\sim$ 29.7 km s^{-1}. An observer at the outskirts of the solar system and in the plane of Earth's orbit would see the velocity of the Earth relative to the Sun vary sinusoidally between +29.7 and -29.7 km s^{-1}. On cosmological scales, physical velocities are also generally caused by the orbital motions of galaxies around each other or around a common center of mass such as the deep potential well of a CLUSTER OF GALAXIES. The largest extragalactic physical velocities seen in the nearby universe are found for galaxies orbiting in clusters of galaxies ($\sim$1500 km s^{-1} or $z = 0.005$), kinematics in the central regions of QUASARS and ACTIVE GALACTIC NUCLEI ($\sim$10 000 km s^{-1} or $z = 0.035$, and our Galaxy's motion with respect to the COSMIC MICROWAVE BACKGROUND reference frame (630 km s^{-1}, $\sim z = 0.002$)

Outside the nearby Universe, redshifts or apparent radial velocities are dominated by the cosmological expansion. This expansion is more properly described as the stretching of the metric or yardstick. In the standard mathematical description of cosmology, the Friedmann–Lemaitre model, distances are defined in terms of the Robertson–Walker metric, the most general mathematical description for a uniform, homogeneous space that is expanding or contracting:

$$ds^2 = c^2\,dt^2 + R^2(t)\left(\frac{dr^2}{(1-kr^2)} + r^2\sin^2\theta\,d\phi^2\right)$$

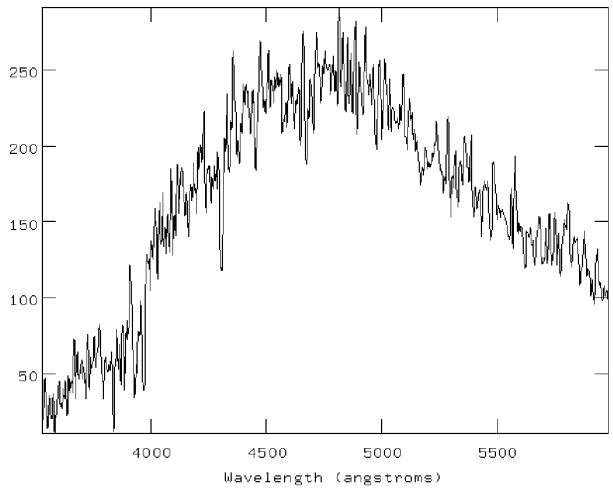
(*a*)



(*b*)

Figure 2. (*a*) The spectrum of a normal galaxy with strong absorption features due to common chemical elements, Ca, Mg, Fe, etc. The redshift of the galaxy is $z = 0.0455$ ($cz = 13\,624$ km s^{-1}). (*b*) The spectrum of a galactic star similar to the stars dominating the light of the galaxy in (*a*), but at a redshift near zero. The strongest absorption lines seen in both the star and the galaxy are the CaII doublet at 3933 + 3968 Å and the G-band (a mix of Fe, Mn, Cr and other metals) at 4300 Å. In the star, these features are seen nearly at their rest wavelengths. In the galaxy, the Ca lines have been shifted to 4110 and 4150 Å, and the G-band is nearly at 4500 Å. The 'redshift' is that shift to longer, redder wavelengths.

for spherical coordinates r, θ, ϕ and time coordinate ct. $R(t)$ is the scale factor, a function of time that is specified by the laws of gravity, and k is the curvature constant, either -1, 1 or 0 for an open, closed or flat space geometry.

In an expanding universe, the cosmological redshift of an object is directly related to its distance. Light travels on null geodesics, $ds = 0$. Therefore a burst of light emitted from a source at some coordinate distance r_1 and time t_e will be received by an observer at coordinate $r = 0$ and time t_0, and will be given by

$$\int_0^{r_1} dr/(1-kr^2)^{1/2} = \int_{t_e}^{t_0} dt/R(t).$$

The left-hand side of this equation is constant in time, while the right-hand side evolves as the photons propagate from the source to the observer. If another burst of light is emitted after an interval dt_e, then the integral on the left-hand side is unchanged, so that $dt_e/R_e = dt_0/R_0$. We can consider dt to be the time between peaks of a continuous wave, and since the frequency of the wave is the inverse of the interval between peaks, we have

$$\nu_e/\nu_0 = \lambda_0/\lambda_e = 1 + z = R(t_0)/R(t_e).$$

Thus photon wavelengths simply stretch with the universe. For small separations, the redshift z is proportional to the distance D to the galaxy, $cz = H_0 D$, where

$$H_0 = \frac{\dot{R}(t)}{R(t)}$$

is the HUBBLE CONSTANT, named for the discoverer of the expansion of the Universe. The form of this equation is the reason that redshift is often quoted as apparent radial velocity, cz. Note that there is no special relativistic $1/(1 + v^2/c^2)$ correction applied—apparent radial velocity is just cz.

There are several definitions of distance in cosmology. The proper distance to an object is the integral of the scale factor over the metric:

$$D_P = R(t) \int_0^{r_1} \frac{dr_1}{\sqrt{1-kr_1^2}} = \frac{R(t)}{\dot{R}(t)} cz$$

which again reduces to the standard redshift–distance relation

$$D_P = \frac{cz}{H_0}.$$

Other definitions of distance are defined by physical properties of objects, and include luminosity distance and angular diameter distance. These different distances are also described in any specific COSMOLOGICAL MODEL in terms of the redshift and the scale factor $R(t)$.

Another key parameter for observers and theorists alike is the lookback time to a given redshift. This depends not only on the Hubble constant but also the specific cosmological model. For variants of the Friedmann–Lemaitre models we have been considering, lookback time is given by the integral equation

$$t_0 - t_1 = H_0^{-1} \int_0^{z_1} (1+z)^{-1}[(1+z)^2(1-\Omega_M z) - z(2+z)\Omega_\Lambda]^{-1/2} dz$$

derived by Caroll, Press and Turner (1992 *Ann. Rev. Astron. Astrophys.* **30** 499). Here Ω_M is the ratio of the mean matter

Dirac House, Temple Back, Bristol, BS1 6BE, UK

density of the universe to the closure density and Ω_Λ is the effective density in a cosmological constant

$$\Omega_\Lambda = \frac{\Lambda}{3H_0^2}.$$

The first significant extragalactic redshift was that of the ANDROMEDA GALAXY (M31) measured by Vesto Slipher in 1912. EDWIN HUBBLE discovered the empirical linear correlation between redshift and distance for nearby galaxies in the late 1920s, although we now know that Hubble's original redshift–distance relation, 600 kilometers per second per megaparsec, was nearly a factor of ten too steep—today's value lies near 65 km s^{-1} Mpc^{-1}. A modern version of the redshift–distance relation based on type Ia SUPERNOVAE is shown in figure 1.

Redshifts are measured spectroscopically by measuring the shift of spectral features of known wavelength and frequency. This is done by either measuring individual lines such as the 21 cm emission line of neutral hydrogen in the radio or the strong absorption features found in the atmospheres of cool giant stars that dominate the optical spectrum of most galaxies, or by cross-correlating the galaxy spectrum with a template spectrum of a similar star at known redshift. The spectrum of a galaxy which is at a redshift of 13 624 km s^{-1} is shown in figure 2 along with that of a star in our own galaxy at a redshift near zero (see also GALAXIES AT HIGH REDSHIFT).

In the last few decades, astronomers have begun to map the nearby Universe by measuring redshifts for samples of thousands of galaxies (see GALAXY REDSHIFT SURVEYS). Maps such as that shown in figure 3 have revealed the complex tapestry of the large scale distribution of galaxies.

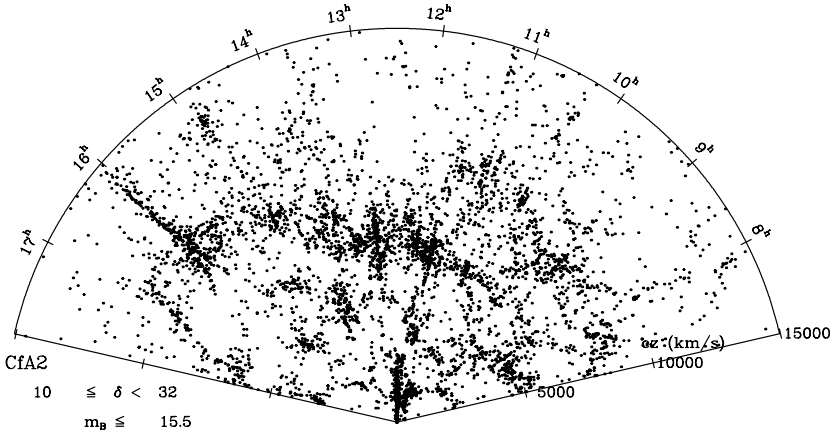

Figure 3. A redshift survey of a broad slice of the nearby Universe. The view is down on a wedge similar to a slice of an orange that is 22° thick and extends out to $z = 0.05$ ($cz = 15\,000$ km s^{-1}). Each point represents a galaxy and there are approximately 5600 galaxies in the plot. We are at the origin or apex of the wedge. The large structure crossing the wedge is the Great Wall of galaxies. The structures that point at the origin are clusters of galaxies; the individual galaxies in each cluster are actually in a relatively small volume of space but appear stretched out towards and away from the observer (the origin) when plotted in redshift space due to the physical motions of the galaxies orbiting each other in the gravtational potential well of the cluster. In real space, they would appear essentially all at the same distance, about the mid-point of the 'finger of God'.

Reference Frames and Time Scales in General Relativity

In relativity one considers events to be described by points in a four-dimensional SPACE-TIME manifold. Let x^μ ($\mu = 0, 1, 2, 3$), be a set of coordinates in a certain part of the space-time manifold. $x^0 = ct$ is a time coordinate t multiplied by the speed of light, c, to gain the dimension of length. $x^i, i = 1, 2, 3$ are three spatial coordinates. If such a coordinate system is actually used in practice (e.g. for some EPHEMERIDES of solar system bodies) it is also called a reference system. A reference frame presents a materialization of a reference system. This materialization is obtained by association of some observed events with corresponding space-time coordinates. In astronomy, observations of satellites, solar system bodies, stars or extragalactic radio sources can be employed for that purpose (see SPACE AND TIME REFERENCES, CONCEPTS).

To describe the observables theoretically in a coordinate-independent manner a so-called local reference frame is often introduced. Such a local reference frame is defined by a set of four orthogonal unit vectors $e^\mu_{(\alpha)}$ ($\alpha = 0, 1, 2, 3$) moving with the observer. $e^\mu_{(0)}$ is related with the passage of time as experienced by the observer and $e^\mu_{(i)}$ $i = 1, 2, 3$ present three spatial reference directions.

Metric tensor and coordinates

The fundamental object of relativity and Einstein's theory of gravity is the so-called metric tensor $g_{\mu\nu}$ of space-time. This metric tensor describes the infinitesimal distance ds between two neighboring points x^μ and $x^\mu + \mathrm{d}x^\mu$ by

$$\mathrm{d}s^2 = g_{\mu\nu}\,\mathrm{d}x^\mu\,\mathrm{d}x^\nu$$

where a summation over $\mu, \nu = 0, 1, 2, 3$ is implied. This means:

$$\mathrm{d}s^2 = \sum_{\mu=0}^{3}\sum_{\nu=0}^{3} g_{\mu\nu}\,\mathrm{d}x^\mu\,\mathrm{d}x^\nu.$$

In the absence of gravitational fields one can choose Cartesian inertial coordinates such that the metric tensor takes the simple form

$$g_{\mu\nu} \equiv f_{\mu\nu} = \mathrm{diag}(-1, 1, 1, 1)$$

which means:

$$g_{00} = -1$$
$$g_{ii} = 1$$
$$g_{i0} = 0.$$

This form is valid in any of such inertial coordinate systems; from this one finds that if $(ct, \mathbf{x})$ and $(ct', \mathbf{x})$ are two such coordinate systems, where the two origins move with constant speed relative to each other, the two systems are related by a *Lorentz transformation*. If the velocity is in the direction of common x-axes this transformation reads:

$$t' = \frac{t - vx/c^2}{\sqrt{1-(v/c)^2}}; \quad x' = \frac{x - vt}{\sqrt{1-(v/c)^2}}.$$

One basic property of the metric tensor is its relation with the proper time τ indicated by some (idealized) atomic clock. Let $z^i(t)$ describe the motion of the clock in the chosen coordinate system then ($\mathrm{d}z^0 = c\,\mathrm{d}t$)

$$\mathrm{d}s^2 = -c^2\,\mathrm{d}\tau^2 = g_{\mu\nu}\,\mathrm{d}z^\mu\,\mathrm{d}z^\nu.$$

If gravitational fields are considered, the metric tensor has to be determined by Einstein's field equations of Einstein's theory of gravity (general relativity theory, GRT). The so-called post-Newtonian framework presents a slow-motion weak-field approximation to GRT. To lowest order, the gravitational potential U enters the time–time component of the metric tensor:

$$g_{00} = -1 + \frac{2U}{c^2} + \mathrm{O}(c^{-4}).$$

For the motion of solar system bodies the post-Newtonian metric must be developed to higher powers of c^{-1} and can be written in the form

$$g_{00} = -1 + \frac{2w}{c^2} - \frac{2w^2}{c^4} + \mathrm{O}(c^{-5})$$

$$g_{0i} = -\frac{4}{c^3}w_i$$

$$g_{ij} = \delta_{ij}\left(1 + \frac{2w}{c^2}\right) + \mathrm{O}(c^{-4}).$$

Here, δ_{ij} is the Kronecker symbol, the scalar potential w generalizes the Newtonian potential U and the vector potential w_i describes magnetic-type gravitational effects related for instance with the Lense–Thirring acceleration due to the gravito-magnetic effect in a rotating body.

Barycentric and geocentric coordinates

Let (ct, x^i) be barycentric coordinates with origin at the center of mass of the whole solar system. If we forget about the rest of our universe and consider our solar system to be isolated we might choose these coordinates to extend to infinity such that far from the origin the metric tensor approaches $f_{\mu\nu}$. Such coordinates are called global, asymptotically Minkowskian (barycentric) coordinates. They play an especially important role in ASTROMETRY and the definition of an international celestial reference system (ICRS).

Let (cT, X^a) be coordinates moving with the Earth. If the origin is chosen by the vanishing of the (relativistic) Earth's mass dipole moment these coordinates are called geocentric. In both barycentric and geocentric coordinates the post-Newtonian metric tensor can be written as indicated above; with (w, w_i) in the barycentric system and (W, W^a) in the geocentric one. One usually requires the external part of geocentric metric potentials resulting from the gravitational fields of solar system bodies apart from the Earth to vanish at the geocenter. This implies that the geocentric metric equals $f_{\mu\nu}$ given above (i.e. the Minkowski metric) at the geocenter if we forget about the potentials from the Earth itself.

Various time scales: TCB, TCG, TT, TAI and TDB

The barycentric coordinate time t is called TCB; the geocentric coordinate time T is called TCG. Let us consider the reading τ of some (idealized) atomic clock in the vicinity of the Earth. From the geocentric metric tensor one infers that τ is related with $T = \mathrm{TCG}$ by

$$\frac{\mathrm{d}\tau}{\mathrm{d}T} = 1 - \frac{U}{c^2} - \frac{1}{2}\frac{\mathbf{V}^2}{c^2} + \mathrm{O}(c^{-4}).$$

Here, $\mathbf{V}$ is the geocentric coordinate velocity of the clock and U is the total geocentric gravitational potential at the location of the clock (the Earth's gravitational potential plus tidal terms resulting from other solar system bodies).

The SI second is related to proper time indicated by a clock. Since the relation of proper time to coordinate time involves the coordinate velocity of the clock and the gravitational potential at the location of the clock, for the definition of an operationally defined geocentric time scale (TT = terrestrial time), one has to specify the relation of TT with the proper time of certain, carefully selected clocks.

At present the definition of TT involves the geoid: TT is a time scale that differs from $T = \mathrm{TCG}$ uniquely by a constant rate, its unit of measurement being chosen such that it agrees with the SI second on the rotating geoid. This implies

$$\mathrm{TCG} - \mathrm{TT} = L_G \times (\mathrm{JD} - 2\,443\,144.5) \times 86\,400\ \mathrm{s}$$

where JD is the Julian continuous count of days. The bracket vanishes on 0h, 1 January 1977. One has:

$$L_G \simeq 6.969\,29 \times 10^{-10}.$$

Here, the constant L_G is determined by the gravitational potential at the geoid, U_0, by $L_G = U_0/c^2$. Because of the problems with the geoid definition, the definition of TT will likely become independent of the geoid in the future. INTERNATIONAL ATOMIC TIME (TAI) is derived as a weighted mean over the readings of several atomic clocks, reduced to the geoid. At present, TAI is related to TT by

$$\mathrm{TT} = \mathrm{TAI} + 32.184\ \mathrm{s}$$

where the additive constant has purely historical origin.

The relation between barycentric and geocentric coordinates takes the form of a generalized Lorentz transformation. Let $\mathbf{z}_E, \mathbf{v}_E$ be the barycentric coordinates and coordinate velocity of the geocenter, U^{ext} the gravitational potential produced by all solar system bodies apart from the Earth then the TCB − TCG relation is given by

$$\mathrm{TCB} - \mathrm{TCG} = c^{-2}\left[\int_{t_0}^{t}\left(U^{\mathrm{ext}} + \frac{1}{2}\mathbf{v}_E^2\right)\mathrm{d}t + \mathbf{v}_E\cdot(\mathbf{x} - \mathbf{z}_E)\right] + \mathrm{O}(c^{-4}).$$

The numerical expression for TCB − TCG can be evaluated from the positions and velocities of the solar system bodies from this expression by numerical integration. Approximate formulae have been derived by Hirayama *et al* (1987) and by Fairhead and Bretagnon (1990). Note that the rates of TCB and TCG differ. This secular term is given by

$$(\mathrm{TCB} - \mathrm{TCG})_{\mathrm{secular}} = L_C \times (\mathrm{JD} - 2\,443\,144.5) \times 86\,400\ \mathrm{s}$$

with

$$L_C \simeq 1.480\,83 \times 10^{-8}.$$

Finally, another barycentric time scale is called TDB (sometimes also denoted by TB). This time has no official status, but is still used especially for solar system ephemerides and spacecraft navigation. According to IAU recommendations from 1979, TT and TDB should differ only by periodic terms leading to the serious problem that such a TDB time scale cannot be realized rigorously because of arbitrarily long periods in the motion of the solar system. Approximately we have

$$\mathrm{TCB} - \mathrm{TDB} = L_B \times (\mathrm{JD} - 2\,443\,144.5) \times 84\,400\ \mathrm{s}$$

with $L_B = L_C + L_G \simeq 1.550\,52 \times 10^{-8}$.

Dynamically and kinematically non-rotating geocentric coordinates

The relation between barycentric and geocentric spatial coordinates, x^i and X^{a} respectively, can be written in the form

$$x^i = z_E^i(T) + e_{(a)}^i(T)X^a + \cdots,$$

where quadratic and higher-order terms in X^a have been dropped. This generalizes the result from a Lorentz-transformation. Two possibilities exist:

- rotationally inertial (dynamically non-rotating) or
- fixed-star oriented (kinematically non-rotating).

A *dynamically non-rotating* reference system is a locally inertial system with relation to rotations characterized by the vanishing of Coriolis and centrifugal forces in some dynamical equation of motion for a test body. It is a remarkable fact that, due to relativistic effects, local inertial axes *precess* with respect to the fixed stars. For a geocentric reference system this precession is mainly given by the so-called *geodesic precession*, resulting from the motion of the Earth–Moon system about the Sun. The angular velocity of geodesic precession amounts to 2″ per century.

In contrast to these dynamically non-rotating systems *kinematically non-rotating systems* cannot be defined locally; instead their definition involves the globally defined coordinate system, comprising the asymptotic regime where the celestial sphere is defined. Then a (local) system is called kinematically non-rotating if the spatial coordinate lines differ from the corresponding global ones only by scale factors but not by their orientation in space, i.e. they are simply defined by $e_{(a)}^i = \delta_{ia} \times$ (scale factors).

To have a simple relation of the geocentric spatial coordinates with reference catalogs (implying a simple relation between the satellite frame and the VLBI frame) kinematically non-rotating systems are clearly preferred.

Reflecting Telescopes

All the earliest optical telescopes were REFRACTORS, using lenses to form an image; they date back to at least 1608. Since light of different wavelengths is bent or 'refracted' unequally as it passes through glass, a refractor always gives a certain amount of false color round an image such as that of a star. Light of whatever color is however reflected in the same direction, so a REFLECTOR does not suffer from this chromatic aberration. The first practical optical reflecting telescope was made by Isaac Newton around 1668.

In a Newtonian reflector, there is no lens to collect the light. The light passes down a tube and falls upon a concave mirror. The mirror sends the light back up the tube onto a smaller, flat mirror placed at an angle of 45°. The light is then directed into the side of the tube and is brought to focus. The image is formed outside the incoming light beam and is enlarged by an eyepiece lens—the observer's head does not obstruct the incoming beam (see NEWTONIAN TELESCOPE).

The Newtonian pattern is still widely used by amateur reflectors of the 6 inch to 20 inch (15 to 50 cm) class. The lower limit to the useful size range is set by the proportion of light to the main mirror which is obstructed by the flat mirror and its support. The upper limit is weaker and is set by the convenience of access to the eyepiece, say at the height of a standing man or woman, although larger telescopes may have a Newtonian focus accessed by ladders. The 72 inch (1.9 meter) Radcliffe Telescope, originally erected in 1948 at Pretoria in South Africa and later moved to Sutherland in 1974, was the largest Newtonian telescope constructed (equal to the size of the Rosse reflector of 1845). Its Newtonian focus is accessed from a cage attached to the dome shutter mechanism—this facility (intended for photography) is almost unused nowadays.

For larger apertures than, say, 50 cm, the CASSEGRAIN TELESCOPE, invented in 1673 is more convenient. Here the secondary mirror is convex and is placed between the main mirror and its prime focus, reflecting the light to the main focus of the telescope, through a hole in the main mirror. The combined action of the two mirrors lengthens the focal length of the telescope above the focal length of the primary mirror alone, but makes the telescope more compact. The combination of concave and convex mirrors also reduces the off-axis aberrations introduced by the primary mirror. The focus of a Cassegrain telescope is close to the observing floor, and as convenient to access as the telescope mounting will allow. The reduction in overall length of a Cassegrain telescope (compared to a Newtonian telescope) directly reduces the size of the building in which it is housed, with consequent saving of costs. Thus, Cassegrain telescopes quickly became popular for astronomical use, and still are, largely because they are much shorter and more compact than Newtonians and are therefore much easier to handle and less expensive.

The next major developments in making reflecting telescopes were due to William Herschel. He made his own mirrors and telescopes, of altazimuth design. With one of these, a reflector of 6.2 in (16 cm) aperture and 7 foot (2.1 m) focal length, he discovered the planet Uranus in 1781. His largest telescope had a mirror 49 in (1.5 m) across. It was not surpassed in size until 1845, when the third Earl of Rosse, in Ireland, produced a Newtonian telescope with a 72 in (1.9 m) mirror. Despite the limitations of its extraordinary mounting (it swung on ropes and chains between two massive stone walls on which the observing platform was mounted, to access the eyepiece), and its cylindrical tubular mounting (which trapped heat and, potentially, degraded seeing), the Rosse telescope discovered the spiral forms of the objects we now know to be external galaxies. The telescope was restored to working order (although not with its original mirror) in 1998.

The early reflectors had 'speculum' mirrors of low reflectivity and did not produce bright images. The metal mirrors tarnished quickly and had to be regularly re-polished, whereas refractors required practically no maintenance at all. It became possible to make glass mirrors, which could be coated with a highly reflective substance such as silver or aluminum. In modern times, the reflection coating can be optimized to the wavelength bands used by the telescope, e.g. the infrared.

As telescopes, whether refractors or reflectors, track a star, or point to different stars in the sky, their attitude changes relative to the vertical and thus to the direction of gravity. This produces mechanical flexure not only of the telescope structure but also of the glass lenses or mirrors, causing degradation of the images. The mechanical rigidity of glass held at the edges limits the size of lenses to about the 40 inch (1 m) size of the Yerkes refractor, made 1895. A mirror, on the other hand, can be supported over the whole of the back of the mirror. Supporting mechanisms or mirror mounts were developed to spread the support evenly and to be effective at all attitudes of the mirror.

Reflecting telescopes are typically made with a paraboloidal primary mirror, which, if perfectly formed, correctly focuses light from a star on its optical axis to a diffraction-limited point image. Off-axis, however, the images are aberrated by coma. A large reflecting telescope thus has a small field of view, perhaps only an arc minute or two, unless a correcting lens is used just ahead of the prime focus. A corrector lens combined with its 3.9 m hyperboloidal primary mirror enables the Anglo-Australian Telescope to have a field of view of up to 1°. The hyperboloidal primary mirror is combined with an ellipsoidal secondary mirror in the AAT's Ritchey–Chrétien optical design.

For survey purposes, such as to make a photographic atlas of the whole sky, an even larger field of view is a great advantage. In 1930, an entirely new optical system was developed by an Estonian researcher, Bernhard Schmidt, with a modified system invented in 1941 by Dmitri

Maksutov. In these reflecting telescopes, the incoming light is collected by a main mirror which is spherical rather than paraboloidal. Normally this would introduce serious image distortions, but these are removed by means of a glass corrector plate fixed at the upper end of the tube. The SCHMIDT TELESCOPE corrector has a complex aspheric profile, the Maksutov corrector has spherical surfaces. The detector, say a photographic plate, a photographic film, or a mosaic of CCDs, is situated at the prime focus. The main problem is that the focal plane is curved, and so the detector has to be shaped to the surface of a sphere. A special plate-holder has to be used to bend a glass photographic plate into the correct form, or the CCDs have to be mosaicked onto a spherical surface. The end result is that sharp star images can be obtained over very wide fields, often well over 10° across. The Oschin Schmidt telescope at Palomar, in California, has a 48 in (1.2 m) corrector plate feeding its 1.8 m primary mirror and was used to make the Palomar Observatory Sky Survey of the northern hemisphere. It is optically similar to the UK Schmidt Telescope in Siding Spring Observatory. The 1.35 m Schmidt at Tautenberg, in Germany, is the largest Schmidt telescope of classical design, whose size is limited by the same issue of support of the optical corrector lens as has restricted refractors to the 1 m class. However, a 4 m Schmidt telescope, LAMOST, is under construction near Beijing for multi-object spectroscopy. Its spherical mirror is fed by a celostat on whose almost flat reflecting surface the appropriate corrections are figured.

In 1908 George Ellery Hale masterminded a 60 in (1.5 m) reflector, which was set up on Mount Wilson in California. It was not so large as the Rosse 72 in, but had a silvered glass mirror and a fully maneuverable equatorial mounting. The tube was a structure of rigid, triangular, skeletal girderwork, rather than being solid walled tube. This reduced weight, improved air flow and seeing, but held all the optical components in exactly the right positions. Most modern reflectors have similar open support structures, which nevertheless are referred to as telescope 'tubes'.

Another design driver, for the tube of telescopes like the 4 m UK InfraRed Telescope on Mauna Kea, the largest designed specifically for infra-red use, is the desire to reduce the amount of structural material intruding into the infra-red beam, so as to limit the thermal radiation created as infra-red background in the telescope.

Hale made a 100 in (2.5 m) equatorially mounted reflector, again set up on Mount Wilson and financed mainly by a Los Angeles millionaire, John D Hooker, after whom it is named. Before he died, Hale planned the reflector with a 200 in (5 m) mirror on Mt Palomar named in his honor. The Hale telescope was completed in 1948 and was the largest telescope in the world for a generation, with epoch-making discoveries to its credit too many to list. The telescope incorporated the 'Serrurier Truss,' newly invented by Mark U. Serrurier of CalTech in Pasadena in 1935 as a way of controlling flexure in the tube of the telescope that he helped to design. Serrurier conceived of a structure that bent as little as possible, but if it did deflect (as was inevitable to some extent), it kept the primary and secondary mirrors in the correct relative positions. The telescope tube includes a cubical section at its center of gravity where the declination axis is attached. Eight triangular trusses are fixed to the corners of the cube, four pointing up to the top end ring which supports the secondary mirror, and four to the primary mirror cell. Four opposite pairs of the triangular trusses oppose bending by gravity, while the four interposed pairs form a parallelogram with the end-rings such that motion of the end rings is of equal magnitude and in parallel, thus keeping the optical elements collimated in spite of flexure. The Gemini telescopes use a variant of this principle, with the large cubical sections at the center of gravity eliminated because of their effect on thermal input into the light beam of the telescopes.

A telescope has two principal degrees of freedom, the axes around which it rotates to point to and follow a star. To a first approximation, an equatorially mounted telescope tracks by rotation about one axis, at constant speed. However, mechanical flexure changes the optical axis of the telescope with two additional degrees of freedom. The change of focus, whether due to mechanical flexure or thermal expansion, is another. Although the telescope mounting structure will have been made to the highest standards, nevertheless the axes will not be exactly orthogonal, nor aligned exactly on the sky. Its bearings will not be exactly circular nor exactly centered, and the gears that drive the telescope will have periodic errors introduced in their manufacture. Refraction of starlight by the curvature of the atmosphere means that the sky does not appear to rotate uniformly. All these effects limit the accuracy of telescope performance.

With the development of computers, it was possible to coordinate the motions of the telescope structure at a high enough rate to compensate for these departures from ideal. In 1974, building on the experience of radio astronomers in controlling altazimuth radio telescopes, the 3.9 m Anglo-Australian Telescope successfully implemented computer control of its equatorially mounted structure at the arc second level. This paralleled the successful computer control of altazimuthally mounted optical NASMYTH TELESCOPES, like the 6 m Bolshoi Teleskop Azimutalnyi (BTA). Virtually all the current generation of large telescopes (over 4 m) are altazimuth designs. The BTA telescope, however, revealed just how important it was to control the thermal environment of a large mirror, otherwise diurnal changes of temperature propagate into the mirror, causing an ever-shifting pattern of thermal distortion.

Symmetrically oriented in gravity, altazimuth telescopes can be made stiffer, and hence could respond better to control. The dome can be fitted more symmetrically around an altazimuth telescope, made more compact and cheaper—the less money of a telescope project spent on a building, the more that can be spent on the telescope and its instrumentation.

The Gemini Telescopes at 8 m, the four telescopes of the VLT at 8.2 m and the Subaru Telescope at 8.3 m have probably reached the practical limit of a thin monolithic mirror, whose optical figure is computer controlled by actuator pads—the transportation of such a mirror from the factory to the site is a major issue, solved in the case of the BTA in the then Soviet Union by construction of a special railway. To transport the monolithic mirrors of the 8 m Gemini telescopes, roads were widened, the radius of curvature of bends reduced and detours constructed around low bridges.

To make larger aperture reflecting telescopes, the solution is to make a segmented mirror, in which the various smaller components are fitted together to make the correct optical curve. This technique was developed in reflecting telescopes working at wavelengths longer than light, such as the James Clerk Maxwell Telescope on Mauna Kea for sub-millimeter wave astronomy, where 276 individual panels are assembled into a mosaic, each of which can be moved by 3 motorized adjusters. Its first realization for optical astronomy was in the original 4.5 m Multi-Mirror Telescope in Arizona, before its six mosaicked mirrors were replaced by a monolithic 6.5 m.

The Keck telescopes, also on Mauna Kea, have hexagonal reflecting mirrors 12 m across (10 m diameter effective circular area). Each hyperboloidal mirror is made up of 36 hexagonal segments, 1.8 m in diameter, fitted into a honey-comb pattern like tiles. Although each telescope is more than twice the aperture, and four times the area of the Palomar 200 in (5 m) telescope, the total mass of glass in each is little more than 14 tons—about the same as the Palomar mirror. The Gran Telescopio de Canarias, under construction for La Palma, also has a similarly segmented 12 m diameter mirror, essentially replicating the Keck

design. As the largest telescopes in the world, the Keck telescopes are setting the pace of discovery among optical observatories.

The overall mirror figure of a segmented mirror is typically maintained through active computer control of the mirror support system, referenced to laser beams. In active optics, the shape of the main mirror is continually modified by computer-controlled pads behind it, so that the shape can be maintained very precisely when the mirror is moved around to point to different directions in the sky. Acceptance that the mirror will bend and provision of a compensating control mechanism makes it possible to reduce the thickness of a mirror, reducing its weight and the strength of the telescope support, and the thermal inertia of the mirror, with benefits in thermal distortion and cost reduction. An alternative method to reduce mirror mass is through a hollow honeycomb construction of the mirror material, used in the two telescopes of the Large Binocular Telescope with 8.4 m mirrors.

With adaptive optics, a relatively bright star in the field of view is monitored, either a naturally occurring star or an artificial star generated in the upper atmosphere by a laser beam. Reacting to the degradation of the image of the monitor star, a flexible optical component in the telescope beam (a small mirror) is continuously modified in shape, to remove distortions due to turbulence in the Earth's air. This technique is more effective at infra-red wavelengths, as optimized in the design of the 8 m Gemini telescopes, which reach the diffraction limit of resolution.

An alternative approach with large reflectors to increase angular resolution is to combine beams from separate telescopes situated tens or hundreds of meters apart. The two Keck telescopes and the Large Binocular Telescope will be used this way, as will the world's greatest telescope at Parañal in Chile; this is the VLT (Very Large Telescope) which will use four mirrors, each 8 m across, working separately as four powerful 8 m telescopes or together as an interferometer.

Seeing conditions at Parañal and other mountain-top observatories, where large reflectors are nowadays constructed, are excellent, but of course for 'perfect' seeing it is necessary to be above the Earth's atmosphere, and this has been achieved with the Hubble Space Telescope, launched from the Shuttle on 25 April 1990. It has a 2.4 m mirror. The size of the monolithic reflecting mirror of the HST was limited by the capacity of the Space Shuttle's cargo bay. In spite of its relatively small size, the HST is the reflecting telescope with the most impact of modern times. The 8 m Next Generation Space Telescope (NGST) reflecting telescope, optimized as a successor to the HST for observations in the near infrared, will be made of segments which unfold like an umbrella. Thermal distortion of the mirror due to solar, terrestrial and lunar thermal radiation, will be controlled by sunshades and passive thermal radiators. In weightlessness, gravitational deflection will not be an issue!

A completely different approach to the provision of large reflecting telescopes is to make their mirrors of a rotating reflective liquid (mercury), spinning on a vibration-free bearing such that centrifugal force builds up the correct parabolic dish shape (as first proposed by Isaac Newton). The 3 m NASA Orbital Debris Observatory (NODO) telescope in New Mexico and 2.7 m Liquid Mirror Telescope of the University of British Columbia are as far as this technology has been proved, but a 6 m Large Zenith Telescope is under construction and a 42 m equivalent aperture array of 18 10 m telescopes with combined focus is planned. Such telescopes are restricted to staring at the zenith, and can be used to sample the sky, whether for space debris or for stars or galaxies.

Another large innovative reflecting telescopes is the Hobby-Eberly Telescope, a spherical reflector of 91 interchangeable segments forming an 11×10 meter hexagon. The telescope structure is tilted at a fixed angle of 55° above the horizon (35° zenith angle). The structure rotates 360° about a vertical axis. It can be rotated to catch stars and galaxies as they rise or set across the small circle centred on the zenith at 55° altitude, and track them via a moving instrument carriage for long enough for spectroscopy (up to 2.5 hours). The South African Large Telescope (SALT) destined for the observatory at Sutherland is a copy of this design.

It is believed that there are no theoretical limitations to the manufacture of ground based reflecting telescopes up to the 50 m to 100 m class. Design studies are in progress for the OWL (Overwhelmingly Large Telescope) or MaxAT (Maximum size Astronomical Telescope); they will surely be projects with global participation.

Ever since Galileo had such spectacular success in 1608 when he first turned a telescope to the sky, astronomers have been seeking ways to make larger and more accurate telescopes in their quest for more light. The present large telescopes of the 8 to 12 meter class are fine examples of what can be done. Engineers, technologists, scientists, administrators and politicians have been inspired to work together to address questions that, in the 21st century, are the modern equivalent of the questions tackled by Galileo in the 17th century. In the words of astronomer Fred Hoyle, put into the mouth of Britain's Prince Charles at the dedication of the Anglo-Australian Telescope in 1974, 'reflecting telescopes are examples of the sorts of things our civilization does well'.

The largest reflecting telescopes operating or under construction are listed in table 1.

Reflection Nebulae

Dust in interstellar space interacts with light primarily by scattering. When a concentration or cloud of dust happens to be near a bright source of light such as a star or group of stars, the resultant scattered light stands out against the sky background and identifies this cloud as a reflection NEBULA. Given that the source of light is almost invariably starlight, a defining characteristic of reflection nebulae is a continuous spectrum, matching that of the illuminating sources in all spectral features except for the color. The color of reflection nebulae, in most instances, is bluer than that of the illuminating radiation, because the scattering efficiency of interstellar dust particles increases with decreasing wavelength throughout the visible range of the spectrum of light.

Most commonly, reflection nebulae result from the close association of a cloud of interstellar dust and a single dominant stellar source of illumination. The cause for this association can be found in each case in one of three scenarios: most frequently, dense cloud material left over from the formation of a relatively luminous star is being illuminated by the new star. Most of the resulting reflection nebulae are therefore associated with stars known to be young and luminous and relatively abundant, i.e. stars of spectral type B. Stars even more luminous and hotter than B stars emit sufficient ultraviolet radiation to ionize the gas in their surroundings. In this case, the emission from the gas will dominate the spectrum of the resulting nebulae, which are then known as emission nebulae, although a faint scattered light continuum produced by the nebular dust is commonly observable in these objects as well.

The second most common form of reflection nebula results from the scattering of starlight by the dust produced by condensation of particles within a mass outflow from a star itself. Such stars are usually in advanced stages of their evolution and their spectral types are generally characteristic of stars cooler than a B star. In most instances, the mass outflow from such stars is preferentially directed along the axis of rotation of such stars, and the resulting nebulae can be recognized by their bipolar morphology.

The third class of single-star reflection nebulae, containing relatively few members, results from the random encounter of luminous stars and relatively dense interstellar clouds as they move through galactic space. They are distinguished from the reflection nebulae mentioned first on the basis of differences in the RADIAL VELOCITY of the nebula and that of the star, revealing their relative motion with respect to each other. The well-known reflection nebulae in the Pleiades STAR CLUSTER are examples of this third class.

The total number of known reflection nebulae is of order 200, with those located north of -33° declination cataloged by van den Bergh (1966). A fairly complete collection of photographs of reflection nebulae and their environments is shown in the *Atlas of Galactic Nebulae* by Neckel and Vehrenberg (1985–90).

Much fainter than the reflection nebulae illuminated by individual stars are extended nebulosities arising from scattering of the general interstellar radiation field of the MILKY WAY GALAXY by dust in isolated interstellar clouds. While such clouds can be observed as individual structures at high galactic latitudes, at lower galactic latitudes the scattering by multiple, overlapping clouds produces the so-called diffuse galactic light, which contributes about 20% of the overall glow of the Milky Way. In this sense, the entire Milky Way galaxy or any other dusty galaxy is a reflection nebula as well.

Reflection nebulae as astrophysical laboratories

Since the early days of the twentieth century and the work of Slipher, Hertzsprung and Hubble (1922), reflection nebulae have attracted the attention of astrophysicists. Much of observational astrophysics deals with the interaction of matter and radiation in cosmic environments, and reflection nebulae are extremely useful laboratories for such studies. The density of the illuminating radiation is typically a few hundred times higher than generally available in interstellar space, which makes the interactions more easily observable. The variable angular offset from the illuminating star provides a mechanism for varying this density over a large range; and the choice of nebulae with illuminating stars of different temperatures allows one to study the effects of radiation fields with varying fractions of ultraviolet light on the dust and gas in these nebulae. Over the years, particular attention has been focused on a number of important astrophysical processes, among these the studies of light scattering by dust; the heating of dust particles by stellar radiation, in particular the stochastic heating of nanoparticles and the resultant non-equilibrium thermal radiation; the photoluminescence by dust particles, also known as extended red emission; the excitation of the near-infrared emission bands, now attributed to small aromatic hydrocarbon particles; the excitation of fluorescence by molecular hydrogen and the photodissociation of the molecules associated with this process; and the far-infrared thermal emission by dust grains heated by starlight. In the remaining sections, these topics and their relationship to reflection nebulae will be reviewed briefly.

Dust scattering properties

The first extensive quantitative studies of reflection nebulae were carried out by HUBBLE, who discovered a close correlation between the apparent magnitudes of the illuminating stars and the angular sizes of a large sample of nebulae, measured on photographs obtained under identical conditions. This suggested that reflection nebulae are largely illumination-bounded, i.e. that their observable extent is set by their surface brightness falling below the level of detectability well before the dust boundary is reached. The constants derived from the observed correlation indicated that the dust albedo, i.e.

the fraction of the light being scattered by an illuminated dust grain, is above 0.5, a result which stands firm to this day.

Scattered light studies involving individual reflection nebulae are complicated by the largely unknown geometry, which leaves unanswered the question of where the scattering dust is located with respect to the plane containing the star. However, two factors help to alleviate this problem. Firstly, since interstellar dust grains scatter predominantly into the forward direction, nebulae in which the dust lies between the star and the observer are expected to be much brighter than nebulae where the dust lies in the same plane as the star or behind the star. The brightest nebulae, i.e. those selected most frequently for intensive study, are therefore invariably cases where the star is located behind the scattering material. Second, modern observing tools allow surface brightness measurements in nebulae over a wide range of wavelengths, from the far-ultraviolet to the near-infrared. Even if the dust/star geometry of the nebulae is not known in detail, an argument can be made that the geometry is the same at all wavelengths, whatever it may be. Important information can thus be obtained from the relative changes that can be seen as a function of wavelength. It is from studies of this kind that we now know that the dust albedo in the near- and far-ultraviolet is generally as high or higher than that derived for the visible by Hubble, and that the degree of forward scattering is increasing with decreasing wavelengths. It has also been found that scattering is still rather effective at near-infrared wavelengths (0.8–2.5 μm), leading to estimates of the dust albedo which exceeds values predicted by current dust models. This difference can be understood if reflection nebulae contain dust grains with larger upper size limits than generally accepted for the diffuse interstellar medium of the Milky Way galaxy. Thus, empirically determined scattering properties of grains in reflection nebulae provide useful constraints for dust models. These characteristics identify the scattering dust grains as particles comparable in diameter to the size of the visible wavelengths. As will be shown below, however, these relatively large grains are only part of the story.

Dust emission by very small grains

Starlight which interacts with nebular dust but is not scattered is absorbed. The absorbed energy, which is mainly in the form of stellar photons of optical and ultraviolet wavelengths, is ultimately re-emitted by dust grains by two processes taking place at longer wavelengths, namely thermal radiation and photoluminescence. Our knowledge of these processes has expanded greatly through studies of reflection nebulae.

The spectrum of the thermal radiation from dust depends on the temperature distribution of the grains and the emission characteristics of the dust materials. Given the relative proximity of the dust to the illuminating star(s) in reflection nebulae, coupled with the fact that the radiation density will decrease with the inverse square of the distance from the star, it was generally expected that grain temperatures in reflection nebulae would be somewhat higher than those found in the diffuse interstellar medium far from any star and that they would span a certain range, e.g. from 30 K to 50 K, versus 20 K in interstellar space. The thermal radiation anticipated from any grains at these temperatures occurs at far-infrared wavelengths longward of 50 μm, and it is indeed observed there. However, a remarkable discovery by Sellgren (1984) demonstrated conclusively that in addition to the expected far-infrared radiation, thermal radiation emerges from dust distributed throughout reflection nebulae which indicates grain temperatures in the range from 500 K to over 1000 K, much higher than expected from equilibrium heating of the larger grains. This additional thermal radiation emerges at near-infrared wavelengths. Grain temperatures in the 500–1000 K range cannot be generated under equilibrium conditions in the nebular environment, because the density of radiation is not nearly high enough. Such high temperatures can be explained only if the radiating INTERSTELLAR GRAINS are so small that the energy of a single stellar photon is large compared with the heat content of the grain, so that its absorption will increase the grain's temperature temporarily to values as high as 1000 K or more. Such grains must be exceedingly small and can contain only between 30 and 100 atoms, with a typical size of 1 nm. Such particles are basically equivalent to large molecules and are referred to as nanoparticles. Stochastically heated nanoparticles were subsequently found by the Infrared Astronomy Satellite (IRAS) to be a common component of the interstellar medium of the Milky Way galaxy as well of other dusty galaxies, where they generate typically about 30% of the total infrared radiation emitted by dust.

Still another unexpected radiative process involving interstellar grains was discovered first in reflection nebulae and continues to be studied in these objects (Witt *et al* 1984). This process is photoluminescence by interstellar grains, also known as extended red emission (ERE). The ERE emerges in the form of a broad, featureless emission band in the 540–950 nm spectral range. An important characteristic of this emission band is that the wavelength of its peak varies both within a given nebula and from nebula to nebula. The determining environmental parameter for this variation appears to be the density of ultraviolet photons. In reflection nebulae, this photon density is a function of the temperature and luminosity of the illuminating star and the distance from the star. One observes that the peak of the ERE band shifts to shorter wavelengths with increasing angular offset, and nebulae with somewhat cooler stars generally show the ERE band with a shorter peak wavelength than those with hotter exciting stars. Recently, the ERE has been detected in the diffuse interstellar medium of the Milky Way galaxy as well, and as expected from the observed behavior in reflection nebulae, the peak wavelength of the ERE, found near 610 nm in the diffuse interstellar medium,

Dirac House, Temple Back, Bristol, BS1 6BE, UK

is shorter than in any nebula, consistent with the fact that the radiation field in the diffuse interstellar medium is of lower density than that found in any single nebula.

Just like the stochastic heating of nanoparticles, the ERE is thought to be a single-photon process involving particles or large molecules in that same size domain. Assuming that the emission of a single ERE photon requires the excitation by a single photon of higher energy, most likely in the ultraviolet, one can estimate from the observed ERE intensities in reflection nebulae and the diffuse interstellar medium that up to 10% of absorbed ultraviolet photons are needed to generate the ERE. This suggests that the ERE is produced by a very common grain species, made from cosmically abundant elements. Current proposals point to oxidized silicon nanoparticles or partially hydrogenated carbon clusters as likely candidates. These same particles are almost certainly also contributing to the non-equilibrium thermal emission at near- and mid-infrared wavelengths, because the ERE process consumes only a fraction of the energies of the exciting photons, the remainder being available to heat the nanoparticles to high temperatures.

Additional evidence for the existence of very small carbonaceous particles with a preferential aromatic bonding arrangement comes in the form of near-infrared emission bands at wavelengths of 3.3, 6.2, 7.7, 8.7, 11.3 and 12.7 μm, which are frequently observed in reflection nebulae. Again, the emitting particles must be excited to an equivalent temperature near 1000 K in order to radiate at these wavelengths. Proposed identifications include polycyclic aromatic hydrocarbon (PAH) molecules or grains composed of amorphous, aromatically bonded hydrocarbon units. These same emission bands have also been observed at correspondingly lower intensities in the diffuse interstellar medium of the Galaxy, indicating that these nanoparticles are ubiquitous throughout space.

Emission from molecules

Many reflection nebulae are associated with star-forming regions. The gas in these environments is typically very clumpy and consists of molecules, predominantly molecular hydrogen. Reflection nebulae are thus also ideal laboratories for studying the interaction of stellar light with this most common form of interstellar molecule. Far-ultraviolet photons with wavelengths shortward of 110 nm cause electronic excitations in hydrogen molecules. The decay of an excited hydrogen molecule is associated with line and continuum luminescence in the 100–165 nm ultraviolet part of the spectrum and a host of emission lines longward of 1 μm in the near-infrared, the latter resulting from cascade transitions between vibrational states of the electronic ground state (Gatley *et al* 1987). Well over 100 of these lines can be seen in bright reflection nebulae. About 10% of the decays of the excited hydrogen molecules result in outright photodissociation of the molecules, which is the primary method by which molecular hydrogen is returned to atomic form in the interstellar medium. The observation and analysis of the ultraviolet and near-infrared emissions from molecular hydrogen in reflection nebulae lead to detailed information about the local densities and radiation field intensities in these hydrogen photodissociation regions. Models which make specific predictions for the relative intensity of the various emission features can thus be tested and used to determine the physical state of the gas in star-forming environments. Again, it was in reflection nebulae that the characteristic ultraviolet and near-infrared luminescence of excited molecular hydrogen was first observed in interstellar space, and these phenomena continue to be studied there with preference.

Reflector

An optical or other telescope that utilizes the reflection of light from one or more mirrors to form an image of a distant object. When reflected from the front surface of a concave mirror (the primary mirror), rays of light from a distant point source, such as a star, initially traveling parallel to the optical axis (the line through the center of the mirror, perpendicular to its surface), converge to a focus where a point-like image of the source is formed. Rays entering at an angle to the optical axis form images at the focal plane, a plane perpendicular to the optical axis that passes through the focus. The size of the image formed at the focal plane is proportional to the focal length of the mirror.

In x-ray reflecting telescopes (like XMM), the x-rays are incident at grazing reflection on to the reflectors and focused into a focal plane. The images are highly aberrated.

In most reflecting telescope systems, the converging cone of light from the primary is reflected from one or more secondary mirrors. In the Newtonian system, the secondary is a small flat mirror that reflects the focus to the side of the telescope tube, where the eyepiece is located. In the Cassegrain and Gregorian systems, and their derivatives, light from the secondary (which is convex in the former and concave in the latter) passes back down the telescope tube, through a hole in the center of the primary, to the eyepiece. Because their secondaries have curved surfaces, they change the angle at which the rays of light reflected from the primary are converging, and so increase the effective focal length and focal ratio of the instrument. A Cassegrain or Gregorian telescope, therefore, has a primary of relatively short focal length, which minimizes the overall length of the instrument, but has a long effective focal length.

The instrumentation used to detect, record or analyze the image (e.g. a photographic plate, electronic detector or spectrometer) can be attached directly at the Cassegrain focus. In large telescopes the instrumentation may be placed directly at the prime focus (the focus of the primary mirror) and, in some cases, the observer can be housed in a 'cage' at the prime focus. In either of these cases, the instrumentation has to swing round with the telescope as it points towards different parts of the sky. To minimize, or eliminate, the need for the telescope structure and mounting to shift heavy instrumentation around, some telescopes incorporate additional mirrors to direct the focus to a fixed plane (e.g. the Nasmyth focus) or a fixed position (the coudé focus).

Although the first design for a reflecting telescope (the Gregorian) was produced in 1663 by the Scottish mathematician, James Gregory (1638–75), the first working reflector was designed and built in 1668 by Sir Isaac Newton (1642–1727), this being the prototype of the Newtonian type. The Cassegrain design was produced in 1672 by the Frenchman, Guillaume Cassegrain, but did not become popular until much later because of the technical difficulties involved in making its convex hyperboloidal secondary. Early reflectors used solid metal mirrors that had relatively poor reflectivities, tarnished quickly and expanded and contracted as the temperature changed. By the late nineteenth century, these had been replaced by metal-on-glass mirrors in which a thin film of reflective metal (silver or, more recently, aluminum) is deposited on the front surface of a glass substrate. The development of low-expansion Pyrex glass in the 1930s greatly improved the performance of reflecting telescopes. Modern mirrors use ultra-low expansion materials such as quartz or ceramics as their substrates.

The largest reflector with a one-piece ('monolithic') mirror is located at the Zelenchukskaya Astrophysical Observatory, Russia. Its primary mirror has an aperture (clear diameter) of 6 m. The largest individual reflecting telescopes are the two Keck telescopes on Mauna Kea, Hawaii, each of which has a primary mirror, 10 m in diameter, which consists of 36 interlocking hexagonal segments.

Refracting Telescopes

Nobody is sure of the date when the first telescope was made. It may be as far back as the early 1550s, when there is evidence that a telescope of some sort was constructed in England by Leonard Digges, but it is all very uncertain, and the first telescope of which we have definite proof was built by the Dutch spectacle maker H Lippershey in 1608. Others soon followed and were turned toward the skies. The first systematic telescopic series of observations was made in early 1610 by Galileo; others had preceded him, but for skill and perseverance Galileo stands alone in those very early days.

His telescope was, of course, a REFRACTOR. It was tiny, and even his most powerful telescopes magnified no more than 30 times, so that they were far inferior to modern binoculars, but they were the direct ancestors of the huge refracting telescopes of today.

In a refractor, the light from the target object is collected by a glass lens, known either as an object glass or as an objective. The light is passed down the telescope and brought to focus, where an image is formed and is enlarged by a second lens, termed an eyepiece or ocular. Note that it is the eyepiece which is responsible for the magnification; the function of the object glass is to collect the light—and, naturally, the greater the amount of light collected, the higher the magnification which can be used. The distance between the object glass and the focus is termed the focal length of the telescope. Magnification is given by the focal length of the telescope divided by the focal length of the eyepiece. The focal length of the telescope divided by the diameter of the object glass gives the focal ratio. Thus if a 3 in (7.6 cm) refractor has a focal length of 36 in (91.4 cm), its focal ratio is $36/3 = 12$ (in metric, $91.4/7.6 = 12$).

Assume now that with our 3 in refractor, with its focal length of 36 in, we use an eyepiece of focal length $\frac{1}{2}$ in. The magnification will be $36/\frac{1}{2} = 72$, often written as $\times 72$.

In theory, and usually in practice, eyepieces are made with a standard thread, so that any eyepiece can be used with any telescope. There is, however, one obvious limitation—the amount of light available depends on the aperture of the object glass (or the main mirror of REFLECTING TELESCOPES). Suppose, with our 3 in refractor, we use an aperture of $\frac{1}{8}$ in. The magnification will then be $36/\frac{1}{8} = 288$. Unfortunately, every time an image is enlarged it becomes fainter, and with this power on this telescope the image would be so faint that it would be completely useless. It is a general rule that the maximum really satisfactory magnification is $\times 50$ per inch of aperture, so that for our 3 in telescope the highest power which can be properly used is $3 \times 50 = 150$. For a higher magnification it is necessary to have a larger telescope. For example, a 6 in refractor of focal length 72 in will have a focal ratio of $f/12$. On this, an eyepiece of focal length $\frac{1}{4}$ in will give a magnification of $72/\frac{1}{4} = 288$, which is quite acceptable. If the focal length of our 6 in refractor is only 54 in, the focal ratio will be $54/6 = 9$. This makes for greater convenience, because the tube is shorter, but to make the f ratio too low will introduce other troubles, and one has to strike a happy mean.

With any telescope it is desirable to have several eyepieces: one to give low magnification and a wide field, suitable for observing objects such as star clusters; one with a moderate magnification, for views of the Moon and planets; one with high magnification, for use on really good, clear nights. With our 3 in, $f/12$ refractor, suitable eyepieces might well be of focal length 1 in ($36/1 = 36$), $\frac{1}{2}$ in ($36/\frac{1}{2} = 72$) and $\frac{1}{4}$ in ($36/\frac{1}{4} = 144$).

The main problem with a refractor is that it introduces what is known as chromatic aberration. Light is really a mixture of all the colors of the rainbow, and the color depends on the wavelength of the light; red light has the longest wavelength for visible radiations, violet the shortest, with orange, yellow, green and blue in between. When a beam of light is passed through a lens, it is split up, and the different colors are bent or refracted by different amounts—red least, violet most. They are therefore brought to focus at different distances from the object glass of a refractor, and an object such as a star is seen to be surrounded by gaudy colored rings which may look superficially attractive but which are most unwelcome to the astronomer.

The false-color trouble can be reduced by what is termed an achromatic object glass, in which there are several component lenses made of different kinds of glass; the errors then tend to cancel each other out. Some false color always remains, but with a good achromatic objective it is not really serious.

Bear in mind that an astronomical refractor will give an inverted image. In fact any refractor will do this, but in a telescope made for terrestrial use an extra lens system is put into the optical train to make the image erect. However, each time a ray of light passes through glass it is slightly weakened. This does not in the least matter when looking at birds, or ships out at sea, but it matters very much to an astronomer, who is anxious to collect every scrap of light available. Therefore, the erecting lens system is left out, although an erecting eyepiece can always be obtained.

The first known telescopes were refractors; the first REFLECTOR was not made until around 1669, when Isaac Newton believed that nothing could rid the refractor of severe chromatic aberration, and decided to develop an entirely different system (see NEWTONIAN TELESCOPES). Previously, efforts to eliminate false color meant that refractors were made with very long focal length. This does reduce chromatic aberration, but at the expense of making the telescopes very unwieldy. For example, Christiaan Huygens, probably the best observer of the early 17th century, constructed a telescope with an aperture of 2 in and a focal length of $10\frac{1}{2}$ feet and used it to discover Titan, the largest of the satellites of Saturn. He then built a telescope with a focal length of 23 feet, and with it discovered the true nature of Saturn's ring system. The telescope must have been incredibly awkward to use, and even more so were the refractors made and used by

Table 1. Some large refracting telescopes.

Name	Observatory	Aperture (in)	Date of completion
Yerkes 40 in	Yerkes, Williams Bay, WI, USA	40	1897
Lick 36 in	Lick, Mount Hamilton, CA, USA	36	1888
Meudon Refractor	Meudon, Paris, France	33	1889
Potsdam Refractor	Potsdam, Germany	31	1899
Lunette Bischoffsheim	Nice, France	30	1886
Thaw Refractor	Allegheny, Pittsburgh, PA, USA	30	1985
Grosser Refraktor	Archenhold, Treptow, Germany	27	1896
McCormick Refractor	Leander McCormick, Charlottesville, VA, USA	26	1880
26 in Equatorial	US Naval Observatory, Washington, DC, USA	26	1873
Thompson Refractor	Herstmonceux, England	26	1897
Innes Telescope	Johannesburg, South Africa	26	1926
Vienna Refractor	Vienna, Austria	26	1880
Newall Refractor	Athens, Greece	25	1862
Lowell Refractor	Lowell, Flagstaff, AZ, USA	24	1895

another pioneer observer, Hevelius of Danzig (the town now known as Gdańsk). One of Hevelius' telescopes had a focal length of no less than 150 feet, but was so subject to wind disturbance that it could seldom be used to its full potential.

Next came the 'tubeless' telescope. Here, the object glass was fixed to the top of a mast, and the observer sighted it by looking along guide wires which could be used to turn the object glass to the right position. The observer then held the eyepiece by hand. One of Huygens' 'aerial telescopes' had a focal length of 210 feet, and it is said that one refractor with a focal length of 600 feet was planned, although there is no record that it was actually built.

Obviously these long-focus telescopes could never be really satisfactory, but in 1733 a wealthy amateur astronomer, Chester Moor Hall, constructed the first achromatic or compound objective, with one component made of flint glass and the other of crown glass. The idea was taken up by John Dollond, and this led on to what was probably the first 'optical firm' in history. In 1765 John's son, Peter Dollond, took one of his achromatic objectives to the Royal Observatory at Greenwich, and its performance was found to be far better than that of the Observatory's best long-focus telescope. The old aerial refractors promptly became obsolete. Moreover, Dollond's telescopes looked attractive. From about 1783 they were made with brass tubes; when set up on well-made mahogany stands they were easy to use and were fitted with slow motions.

By the first part of the 19th century it had become possible to make really good objectives. Then, in 1862, Thomas Cooke, in England, built the first of the 'great refractors'; it is known as the Newall Telescope and had an objective of 25 in across (it is still in use, at the Athens Observatory in Greece). Between 1870 and 1900 even larger refractors were built, culminating in 1897 with the 40 in telescope which was set up at the Yerkes Observatory in Wisconsin, USA. At the time, and for some years afterwards, it was the most powerful telescope in the world, and it proved to be a great success. It is still in use on every clear night.

Could it be possible to build a refractor of greater size than the Yerkes 40 in? Theoretically, yes, but there were serious practical difficulties. If a lens is too large it will begin to distort under its own weight, and this will make it useless. An attempt was made at the very end of the century, when a 49 in objective was made in France. The 180 foot tube could not be mounted in the conventional way; instead it was left horizontal, and the light was brought to it by means of movable mirrors. The telescope was shown at the Paris Exposition of 1901, but it was clearly a failure, and it was never used for any astronomical work. Before long it was dismantled, and the fate of the object glass is unknown. The fate of a 41 in, destined for the Pulkovo Observatory in Russia, was even worse; before the optics could be completed, the mounting of the telescope had rusted away.

By then it had become possible to build very powerful reflecting telescopes, and these were not subject to size limitation, because a mirror can be supported by its back; light does not have to pass through it. A few large refractors have been made in the 20th century, but not many are used by professional astronomers except for very specialized programs, and it is undeniable that the future of the telescope lies with the reflector.

Yet in amateur hands, the refractor remains ideal. It is much less delicate than a reflector and will need little maintenance; if it is treated with care, it will last a lifetime and more. Although its color correction can never be as good as that of a reflector, it will give superb, clear-cut images.

Choosing a refractor for home use is something to be undertaken with care, because a poor-quality telescope does not betray itself at a glance. Some small refractors are sold according to the power available—or so it is claimed; it one recent advertisement it was said that the telescope offered 'would magnify 750 times'. The aperture of the object glass was however only 3 in, so that the maximum power which could be used to advantage was no more than

150. Aperture is all-important, and a telescope advertised without giving the diameter of the objective should be avoided. Watch too for a ring fixed inside the top of the tube, masking the outer part of the objective and thereby cutting down the aperture; this is a trick designed to conceal defective optics.

Generally, it is not really sensible to spend much money on a refractor with an object glass less than 3 in in diameter. Of course a smaller instrument, such as a 2 in, is better than nothing at all, but given a choice between a very small telescope and a pair of good binoculars it is certainly better to opt for the binoculars.

A refractor of aperture up to 4 in is easily portable, although a larger instrument will be too heavy to move around, and will be best set up in a permanent observatory.

Some large refracting telescopes are listed in table 1.

Refractor

An optical telescope that utilizes the refraction of light through a lens to form an image of a distant object. In essence, a refractor consists of two lenses, an objective (or object glass) and an eyepiece. The objective is a lens of long focal length that collects light and forms an image of a distant object at its focus, or focal plane. The eyepiece is a lens of short focal length that enables an observer to view a magnified image and which may also be used to project an enlarged image onto a screen, photographic emulsion or electronic detector. In practice both the objective and the eyepiece are compound lenses, each consisting of two or more components.

The invention of the refractor, or refracting telescope, is usually ascribed to the Dutch spectacle-maker, Hans Lippershey (*c*. 1570–1619), who is reputed to have discovered the principle in 1608 when, by chance, he noticed that distant objects were seen to be enlarged when he placed one lens in front of another. The first astronomer to make serious use of the refractor was the Italian scientist, Galileo Galilei (1564–1642), who, with a telescope of his own design and construction, made a succession of epoch-making discoveries in 1609–10. The Galilean refractor used a convex ('positive') objective and a concave ('negative') eyepiece that was placed in front of the focal plane of the objective. It produced erect images, but its field of view was very small and the instrument was difficult to use. An improved design, which is the basis of the modern refractor, was published in 1611 by Johannes Kepler (1571–1630). The Keplerian, or 'astronomical', refractor uses a convex objective and a convex eyepiece that is placed behind the focal plane of the objective. Although it produces an inverted image, it has a wider field of view than the Galilean instrument. Because the eyepiece is located on the observer's side of the focal plane, it is possible to focus simultaneously on the image and on micrometer wires placed at the focal plane.

The performance of early refractors was seriously degraded by several optical defects, in particular, chromatic aberration and spherical aberration (the inability of a simple lens to focus all wavelengths and all rays from a point source at the same focal point). Because the effects of these aberrations could be reduced by using lenses of very long focal length, attempts to overcome these problems led, in the seventeenth century, to the development of extremely long and unwieldy instruments, such as the 46 m long refractor constructed in Danzig by Johannes Hevelius (1611–87). Dutch astronomer Christiaan Huygens (1629–95) dispensed altogether with the telescope tube. His 'aerial telescope' consisted of an objective, which was held in a short tube that was hoisted up a mast, linked to and aligned with an eyepiece by means of a taut cord.

The invention of the achromatic doublet (a lens consisting of two components, the combination of which greatly reduced the effects of chromatic aberration) transformed the development of the refractor and rendered the aerial telescope redundant. Following a series of experiments using different types of glass, which he had carried out between 1729 and 1733, the English amateur optician, Chester Moor Hall (1703–71), instructed professional optician George Bass to construct the first achromatic objective in 1733. From 1754 onwards, telescope-makers, notably John Dollond, began to construct good quality achromatic refractors. Greatly improved glass-making techniques, developed by the German astronomer, Joseph von Fraunhofer (1787–1826), enabled larger objectives of higher quality to be produced. The development of the refractor culminated in the construction of the 1 m ('40 inch') refractor at Yerkes Observatory, Wisconsin, USA, which was commissioned in 1897 and remains, to this day, the largest operational refractor in the world. Because reflecting telescopes are easier and cheaper to build, mount and support and do not suffer from chromatic aberration (which cannot entirely be eliminated from a refractor), large refractors are no longer constructed and all large modern instruments are of the reflecting type.

Regiomontanus [Müller, Johann or Johannes] (1436–76)

Born in Königsberg (latinized in his trade name), Mainz (now Germany), a pupil of PEURBACH. Succeeded him as professor of astronomy at the University of Vienna, and became astronomer to King Matthias Corvinus of Hungary. He built an observatory and instrument workshop in Nuremberg. Observed Halley's Comet in 1472 and eclipses of the Moon. This led him to suggest that eclipse timing and techniques that he had used in tracking comets could be used effectively as a clock to determine longitude. Eclipses were in fact too infrequent to be of much use as timing markers, but the general idea was picked up by JOHANN WERNER of Nuremburg and developed into the method of lunar distances (i.e. continuously measuring the distance of the Moon from the Sun). Regiomontanus wrote on calendar reform, and was summoned by Pope Sixus IV to Rome to advise on the topic but died (of the plague or poisoned by his enemies) before he could do so.

Regolith

The loose material covering the surface of a rocky planetary body. Regolith consists of dust and tiny fragments of rock produced by the impact of small meteorites and micrometeorites, and is characteristic of worlds which have no atmospheres and have been essentially geologically inactive for a few billion years. The lunar regolith is 2–8 meters deep on the maria, and as much as 15 meters deep in the highlands, which have had longer exposure to meteoritic bombardment. Its composition largely reflects that of the underlying rock. Mercury has a very similar albedo to the Moon, and is assumed on this basis to possess a similar regolith. Images showing boulders on the surface of the asteroid Ida suggest that it has a regolith.

Regulus

The star α Leonis, apparent magnitude 1.36, a blue-white main sequence star of spectral type B7V. Its name, meaning 'Little King', was given by Nicolaus Copernicus (1473–1543), marking the fact that it had been regarded as one of the leading stars in the sky for some 2000 years. It was one of the four 'Royal Stars' of the Persians, *c*. 3000 BC, who called it Venant, later Miyan ('the Center'); it marked for them the summer solstice, being prominent on June evenings (*see* Aldebaran). At a distance of 78 light-years, it has a parallax of $0.042''$ and absolute magnitude -0.5. There is an eighth-magnitude companion star $2.95'$ distant at position angle 307°.

Reinhold, Erasmus (1511–53) and Reinhold, Erasmus (1538–92)

Father born in Saalfeld, Germany, became professor of mathematicum superiorum (astronomy) at the University of Wittenberg. Influential on BRAHE and KEPLER. Revised a work by GEORG PEURBACH about the motion of the planets and calculated the *Prussian Tables* (*Prutenicae Tabulae Coelestium Motuum*) containing calculations about the movements of celestial bodies. The first such calculations made according to the Copernican theory, they became a basis for the reform of the calendar in 1582.

Relative Sunspot Number

An index of sunspot activity originally devised in 1858 by J R Wolf (1816–93) of the Federal Observatory of Zurich and otherwise known as the Zurich sunspot number. The relative sunspot number, denoted by the letter R, is given by the formula $R = k(f + 10g)$, where g is the number of visible sunspot groups, f is the total number of individual spots visible on the face of the Sun and k is a correction factor that takes account of factors such as the size of telescope used, atmospheric conditions and the performance of the individual observer. For example, if on a particular occasion there were four sunspot groups containing 3, 7, 9 and 12 spots respectively, g would be 4 and f would be 31. Assuming $k = 1$, the value of R would be $1(31 + 40) = 71$.

The relative sunspot number places greater emphasis on the number of groups than on the number of individual spots, because the number of groups is more closely related to the number of underlying active regions. Although the relative sunspot number gives a reasonable guide to the changing level of sunspot activity throughout successive sunspot cycles, sunspot areas give a better measure of the overall level of solar activity.

Relict

Two Soviet astronomical missions. Relict-1 was launched on the PROGNOZ-9 satellite in July 1983. Two small radio telescopes were used to search for any anisotropy (unevenness) in the cosmic background radiation. Relict 2 was launched into a halo orbit at the L2 Lagrangian point, 1.5 million km in the anti-sunward direction, in January 1994. It returned submillimetre wavelength astrophysical and magnetotail plasma data.

Resolving Power

A measure of the ability of a telescope to separate objects that are apparently close together. Resolving power, or resolution, is usually expressed as the minimum angular separation at which two identical point sources of light (for example, two identical stars) can just be distinguished as separate points (if the sources are closer together than this minimum angle, they will appear as a single point). The *smaller* the angular resolving power, the *better* the ability of the telescope to separate close pairs of stars and the greater the amount of detail that will be revealed in the image of an extended object (which can be regarded as consisting of large numbers of points).

The theoretical resolving power, R, of a telescope depends on its aperture (D) and the wavelength (λ) of the light that is being observed. It is given, conventionally, by the Rayleigh limit, whereby $R = 1.22\lambda/D$ (where R is expressed in radians), or $R = 2.52 \times 10^5 \lambda/D$ (where R is expressed in arcsec). For example, for light of wavelength 5×10^{-7} m (500 nm), a telescope of aperture 1 m would have a theoretical resolution of $2.52 \times 10^5 \times (5 \times 10^{-7}/1) = 0.13$ arcsec. By contrast, a telescope of aperture 0.1 m would have a resolution of 1.3 arcsec.

In practice, atmospheric effects limit the resolutions of Earth-based telescopes. Turbulence in the atmosphere smears out star images into disks ('seeing disks') that often are significantly larger than 1 arcsec in diameter. Consequently, the actual resolutions attained even by large telescopes are often poorer than 1 arcsec (the theoretical resolution of a 13 *centimeter* telescope) and seldom, even at the very best sites under the best conditions, better than 0.25 arcsec. Because it orbits clear of the atmosphere, the Hubble Space Telescope, with an aperture of 2.4 m, is able to achieve its theoretical resolving power of about 0.05 arcsec (about 5–10 times better than the largest conventional ground-based telescopes). The deleterious effects of the atmosphere can to some extent be overcome by means of active/adaptive optics or speckle interferometry.

The theoretical resolution of a radio interferometer consisting of two dishes separated by a distance D (the 'baseline') is given (in radians) by $\lambda/2D$, where λ is the wavelength of the observed radiation. For very long baseline interferometers using separations comparable to the diameter of the Earth and wavelengths of around a centimeter, resolutions as fine as 0.001 arcsec can be attained.

Resonance

A resonance in CELESTIAL MECHANICS occurs when some of the quantities characterizing the motion of two or more celestial bodies can be considered as commensurable, i.e. their ratio is close to an integer fraction. In a simplified form, this can be expressed as

$$T_1 : T_2 = p_1 : p_2$$

where T_1 and T_2 are the actual values of the quantities involved, while p_1 and p_2 are positive integers (1, 2, 3, . . .; $p_1 \leq p_2$). Commensurabilities are frequently found in the dynamical behavior of celestial bodies of the solar system, involving widely different regimes of motion: spin, orbit, secular precessions. Although resonances in real systems usually approximate within a given accuracy of the corresponding exact value, they give important information on the existence of symmetries in the motion of the objects involved, leading to peculiar configurations and the periodic recurrence of gravitational interactions.

The resonances that can be more easily revealed among the solar system's bodies involve the orbital periods of two dynamically interrelated objects, e.g. two planets circling around the Sun or two satellites around a planet. They are usually referred to as mean motion resonances because they can be alternatively expressed by comparing the average orbital angular velocity of the bodies. Thus a mean motion resonance ensures the repetition of certain geometrical configurations: as an example, a 1:2 resonance between the orbital periods of two natural satellites implies that, while the inner body completes two orbits around the planet, the outer has made only one, and therefore conjunctions always occur along the same direction in space.

For many satellite pairs of the outer planets a resonant relation can be found at a high level of accuracy. Within the Saturnian system the pairs MIMAS–TETHYS and ENCELADUS–DIONE are both in the 1:2 resonance, TITAN and HYPERION satisfy the 3:4 resonant relation, while the ratio of the orbital periods of Titan and IAPETUS is close to 1:5. The three Galilean satellites closest to Jupiter, i.e. IO, EUROPA and GANYMEDE, represent an outstanding example of a multiple mean motion resonance. The pairs Io–Europa and Europa–Ganymede are both found in a 1:2 resonance: thus the periods of revolution of Io and Ganymede are also in the ratio 1:4. This peculiar resonance, known as the Laplace resonance, prevents the occurrence of triple conjunctions of the three satellites. As far as the planets are concerned, some are indeed found close to mean motion resonances. The so-called great inequality is a 2:5 resonance which rules the motion of the two most massive planets of our solar system, JUPITER and SATURN, while the 2:3 commensurability between NEPTUNE and PLUTO provides the basic dynamical mechanism for avoiding too close approaches between them. For the Saturn–URANUS (1:3) and Uranus–Neptune (1:2) pairs the corresponding resonant relations are satisfied with less accuracy.

The 1:1 mean motion resonance represents an exceptional case, allowing widely different dynamical behaviors depending on the relative mass and position of the bodies involved. The basic dynamical framework is provided by the so-called restricted three-body problem (one of the masses is negligible with respect to the other two) and its special solutions. In particular the two equilateral Lagrangian points, located along the unperturbed orbit of the secondary body around its primary and displaced 60° ahead or behind its current position, are of special relevance because they possess the necessary stability conditions for real systems to exist. The TROJAN ASTEROIDS are in fact grouped around the triangular Lagrangian points of the Sun–Jupiter system. Being historically the first bodies of the solar system discovered satisfying a 1:1 mean motion resonance, the attribute 'Trojan' is now commonly used to indicate the occurrence of this peculiar configuration. Trojan satellites have been also observed and many more are supposed to exist within the crowded systems of the outer planets. This is the case of two of the largest satellites of Saturn: Tethys shares its orbit with the tiny moonlets (a little more than 10 km in size) Calypso and Telesto, each located close to one of the triangular equilibrium points, while Dione is preceded by Helene, a 16 km long irregularly shaped body. When a 1:1 resonance is not exactly satisfied, it may still lead to peculiar trapping mechanisms, such as the so-called tadpole and horseshoe orbits. The motion of the already mentioned Trojan asteroids and those of Janus and Epimetheus, the two small satellites of Saturn sharing almost the same orbit, are well-known examples of this kind. The question whether the Earth itself has Trojans, small enough to have escaped direct observation, has been repeatedly posed. The advent of orbiting telescopes has allowed us to detect the existence of a thin cloud of dust dispersed along the orbital path of our planet, temporarily trapped in the vicinity of the 1:1 resonance (a possible explanation for the origin of the zodiacal light) while the recent survey of the near-Earth asteroid population has allowed us to identify (3575) Cruithne, an object in an unusual Earth horseshoe orbit.

Mean motion resonances are encountered rather often throughout the solar system, more than due to chance, suggesting that they may provide a basic mechanism for long-term stability. Yet the study of the orbital evolution of objects close to mean motion resonances has shown that a wide variety of dynamical behaviors can be expected, including regular and chaotic regimes. Both characterize the resonant structure of the asteroid main belt, the densely populated region of small-sized celestial bodies extending between the orbits of Mars and Jupiter. Opposite trends are in fact observed in the distribution of asteroidal mean distances from the Sun: regions devoid of objects ('gaps') corresponding to low-number mean motion resonances with Jupiter (e.g. 1:2, 1:3, 2:5), as well as concentrations (e.g. 2:3, 3:4, 1:1). Detailed modeling of the individual cases has shown that resonances might be closely surrounded by chaotic regions. This is the dynamical mechanism

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

responsible for the formation of the 1:3 gap: sudden chaotic jumps in the eccentricity of the orbit may have caused a near-resonant asteroid to become a Mars crosser and eventually be removed from the main belt by close encounters with that planet.

The contradictory tendency to prefer certain resonances and avoid others is observed not only in the asteroid belt but also in other densely populated systems, such as planetary rings. When the structure of Saturn's rings is analyzed in the light of resonances, it turns out that the largest relatively empty region observed, i.e. the Cassini division, is strongly related to Mimas, corresponding to the 1:2 mean motion resonance. Smaller-scale features characterizing the A-ring can be also explained by the resonant effects of the satellites Pandora, Prometheus and Janus, orbiting just beyond the main ring system (see also SATURN: RINGS).

More complex, less intuitive orbital resonances are found when the motion of a celestial body is investigated in detail. The presentation of an orbit as an ellipse fixed in space is only valid as long as two bodies alone are gravitationally interacting: distant perturbations by other bodies have the effect of inducing slow changes in the shape and the orientation of an orbit in space. This means that the eccentricity and the inclination are not constant any more, while the apsidal line (i.e. the line joining apocentre and pericentre) and the line of nodes (marking the intersection of an inclined orbit with the local reference plane) may advance, regress or librate in time. Commensurabilities in the rate of change of these quantities are called secular resonances and have been found to play a fundamental role in several problems of solar system dynamics.

The overabundance of resonant configurations can therefore be considered as the result of a long-term selection process: among the multitude of objects once crowding the solar system, only those which could rely on the strong sheltering action of one or more resonances could dynamically survive. An outstanding example of this kind involves Neptune and Pluto: the unusually large eccentricity of the latter if compared with the almost circular orbits of the other planets has the consequence of letting Pluto's perihelion distance become smaller than Neptune's mean distance from the Sun. Although at present the orbits do not cross owing to their mutual inclination and angular parameters, they might, in principle, bring the two bodies dangerously close to each other. Nevertheless, the already mentioned mean motion resonance combined with the motion of Pluto's perihelion prevents Neptune and Pluto from actually reaching their minimum achievable approach distance. The observation of several newly discovered objects sharing with Pluto the 2:3 mean motion resonance gives an indication of the importance of this mechanism in shaping the dynamical structure of the so-called Transneptunian Belt.

Hyperion, the small irregularly shaped satellite of Saturn, is also similarly sheltered from the perturbing action of Saturn's largest moon Titan. Being closer to the planet and moving faster, Titan periodically overtakes Hyperion: when this happens the two bodies experience a minimum approach distance, while their mutual gravitational perturbations reach a maximum. The existence of a resonance allows conjunctions to take place only when Hyperion is at the apocenter of its orbit, namely at the largest possible distance from Saturn and therefore also from Titan.

Exotic resonant mechanisms have also been found within the solar system. The existence of narrow arcs in Neptune's Adams ring has been explained as the observable effect of a 42:43 mean motion inclined resonance between the ring particles and the neighboring Galatea satellite, which then provides the necessary confinement (see also NEPTUNE: RINGS). Also, a peculiar high-number commensurability strongly characterizes the motion of the Moon around the Earth, as witnessed by the existence of the SAROS cycle, a period of approximately 18 yr and 10 or 11 days (depending on the number of leap years in the interval) which has allowed the prediction of solar and lunar eclipses with remarkable accuracy since ancient times. One Saros encompasses 223 lunar synodic months (the time span between two subsequent conjunctions with the Sun) which nearly equals 239 anomalistic months (the time span between two subsequent perigee passages) and 242 nodical months (the time span between two subsequent passages at the ascending node). From a strictly dynamical point of view this means that any configuration of the Earth–Moon–Sun system closely repeats after one Saros.

Resonances are also found when investigating the coupling between the rotation of a celestial body around its own axis and its orbital motion. If a commensurability exists among the corresponding periods, a spin–orbit resonance is said to occur. The Moon, whose rotation period equals its orbital period around the Earth, thus allowing only one side of its surface to be seen from our planet, is a well-known example of a 1:1 spin–orbit resonance. This particular commensurability, called synchronous resonance, is also found for the vast majority of natural satellites in the solar system, suggesting the existence of an underlying physical phenomenon in action. As a matter of fact, the synchronous resonance can be considered as a direct outcome of the long-term tidal interaction between bodies of finite dimensions (see also TIDES). The presence of a tidal bulge raised by the differential gravitational attraction on the surface of a celestial body determines the onset of internal friction, as the bulge is carried along with the rotation. Usually this leads to a slowdown of the spin rate until a 1:1 resonance is achieved, because the bulge is then permanently locked towards the attracting body. Tides are experienced by both bodies, although with different intensity and timescales depending on their relative size, mass and internal structure; thus the end state of a tidally interacting system is achieved when the revolution and the rotation periods of both bodies are equal, i.e. they revolve with their tidal bulges facing each other. This is observed in the

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

case of Pluto and its satellite Charon, almost comparable in size, currently trapped into a fully evolved 1:1 spin–orbit resonance. The Earth–Moon system has only partially evolved (owing to lunar tides the length of the day on our planet is at present increasing at a pace of about 2 ms per century), while the other planets have a mass much too large with respect to that of their satellites to be affected by their tides. Mercury represents an exceptional case: because of its proximity to the Sun it is subjected to strong solar tides and has therefore evolved towards a 2:3 spin–orbit resonance. Its present period of revolution is 87.97 days, while its rotation amounts to 58.65 days, showing that, for every two orbits around the Sun, Mercury completes three rotations around its axis.

Thus, resonances have provided a powerful means to explain many puzzling problems in solar system studies. The chaotic behavior of near-resonant asteroidal orbits has allowed us to discover the long-sought dynamical paths for the transport of matter from the asteroid belt to the inner solar system, since a significant fraction of near-Earth asteroids and of meteorites are thought to have originated by collisional evolution within the main belt. The Laplace resonance involving the innermost Jupiter Galilean satellite Io has been indicated as the ultimate cause for the internal tidal heating mechanism which provides the energy for the intensive volcanic activity observed on the surface of the satellite.

Resonances have proven to be a powerful tool for space mission design. Already in 1974, the US MARINER 10 spacecraft could perform repeated flybys of planet Mercury exploiting a 1:2 mean motion resonance between the spacecraft's period of revolution around the Sun and that of the target planet. The geostationary ring, located along the Earth's equatorial plane at a distance of about 36 000 km above its surface, is now widely used for telecommunication purposes because the 1:1 spin-orbit resonance between the Earth's rotation and the orbital period of a geostationary satellite allows a spacecraft to remain permanently stationed over a given longitude.

On a larger scale, when looking at the Sun and the stars in our Galaxy and the existence of extrasolar planets, resonances are also observed. In the rapidly expanding field of astroseismology, the study of solar oscillations exploits the effect of resonances to detect peculiar structures in the interior of the Sun. The confirmation of the discovery of two planets orbiting around a pulsar (PSR1257+12) has been possible thanks to the existence of a 2:3 mean motion resonance among them, which produced a characteristic signature in their mutual perturbations.

Reticulum

(the Net; abbrev. Ret, gen. Reticuli; area 114 sq. deg.) A southern constellation which lies (to the north-west of the Large Magellanic Cloud) between Dorado and Horologium, and culminates at midnight in mid-November. It was first shown as Reticulum Rhomboidalis (the Rhomboidal Net) on Isaac Habrecht II's celestial globe of 1621 and was renamed by the French astronomer Nicolas L de Lacaille (1713–62), after the reticle in the eyepiece of the telescope with which he measured the positions of the stars of the southern sky in 1751–2. The shortened form was adopted by the IAU in 1922.

A small, inconspicuous constellation, the brightest stars in Reticulum are α Reticuli, magnitude 3.3, and β Reticuli, magnitude 3.8. There are no other stars brighter than fourth magnitude. Interesting objects include ζ Reticuli, a naked-eye double star with two yellow (G1 and G2) components, magnitudes 5.2 and 5.5, separation 5.1′, that have the same proper motion (which is very similar to that of the Sun), θ Reticuli, a close binary with bluish-white (B9) and white (Am) components, magnitudes 6.0 and 7.8, separation 4.1″, and NGC 1559, an eleventh-magnitude barred spiral galaxy.

Retrograde Motion

Angular motion in the opposite sense to the prevailing direction (as opposed to direct or prograde motion, which is in the same sense). Motion of a body in the solar system, either axial rotation or orbital revolution, is retrograde if it is in the opposite direction to that of the Sun's rotation: clockwise as viewed from the Sun's north pole. Bodies in retrograde orbits have orbital inclinations between 90° and 180°; bodies with retrograde rotation have axial inclinations between 90° and 180°. Retrograde motion is the exception to the norm, for it is in the opposite sense to the motion of the rotating disk of material from which the Sun and the planets formed, and hence is indicative of some event in a body's history having modified its motion. Of the major planets, Venus, Uranus and Pluto have retrograde rotation, possibly as a consequence of impacts they suffered at some time in their past. The outermost satellites of Jupiter, Saturn and Uranus, and also Neptune's largest satellite, Triton, have retrograde orbits, indicating that these are captured objects. Many long-period comets have retrograde orbits as a consequence of the circumstances in which they were perturbed inwards from the cometary reservoirs in the distant outer reaches of the solar system.

The term is also used for the temporary apparent motion from east to west on the celestial sphere of a superior planet or minor planet, in contrast to its usual direct eastward motion. This retrograde motion occurs around the time of a planet's opposition. As a planet nears opposition, the Earth is approaching it and travelling faster, and the planet's apparent rate of motion slows down, and then reverses direction. Its retrograde motion is fastest at opposition. The reverse occurs after opposition, when the Earth is moving away from the planet: the retrograde motion slows, halts and returns to direct. The two points at which the motion changes direction are called *stationary points*. Because the planets' orbits are inclined to the ecliptic, which defines the plane of the Earth's orbit, the direct–retrograde–direct sequence causes the planet to describe what is known as a *retrograde loop* on the celestial sphere, or sometimes an S-shaped curve. The more distant a planet, the smaller its retrograde loop.

Compare: direct motion.

Rhea

The largest of the mid-sized icy satellites of Saturn, with a diameter of 1528 km, discovered by Giovanni Cassini in 1672. It orbits at a distance of 527 000 km. The surface was well imaged by Voyager 1. Unlike the other regular mid-sized satellites of Saturn, Rhea shows little diversity of terrain—the surface is saturated with craters. The 250 km diameter crater Izanagi is the exception: the majority of Rhea's craters are around 20 km in size. It has been suggested that this even population of craters was produced by debris from the collision that left the satellite Hyperion, orbiting farther out, with its irregular shape. There are some ridges and scarps, interpreted as resulting from a global compression, as is thought to have occurred on Mercury. The lack of any orbital resonances with other satellites is what has left Rhea for the most part geologically inactive.

Rheticus [Rhaeticus; Lauchen, Georg Joachim von] (1514–74)

Born in Feldkirch, Austria, and started an extraordinary life with the name Georg Iserin. After his father was executed for sorcery and his name was abandoned, Iserin took a germanized form of his mother's maiden name and then the name of Rheticus (the Roman name of the province where he had been born). Taught mathematics and astronomy at the University of Wittenberg, visited COPERNICUS for two years, on the basis of which he published and introduction to the heliocentric theory, the *Narratio Prima* or *First Report to Johann Schöner on the Books of the Revolutions of the Learned Gentleman and Distinguished Mathematician, the Reverend Doctor Nicolaus Copernicus of Torun, Canon of Warmia, by a Certain Youth Devoted to Mathematics*, which established the Copernican hypothesis with credibility. Rheticus negotiated with the authorities for the publication of Copernicus' *De Revolutionibus*, at first publishing the trigonometrical sections, with his own calculation of a table of cosines (the first published). As he neared the end of the preparation of the text of *De Revolutionibus*, he was offered a post at the University of Leipzig at greatly increased salary and left the completion of the task to OSIANDER. Rheticus had to flee a homosexual scandal in Leipzig and found himself in Cracow as a doctor, working in his spare time and with a group of assistants on trigonometric tables, making instruments and observing in astronomy.

Riccioli, Giambattista [Giovanni Battista] (1598–1671)

Italian astronomer, born in Ferrara, became a Jesuit and came into conflict with the Copernican system, like OSIANDER refuting it while acknowledging its use as a mathematical hypothesis. Mapped the Moon and introduced some of the names still used, in a chart published in the *New Almagest* in 1651. As a follower of the Ptolemaic system, he named major lunar craters after HIPPARCHUS, PTOLEMY and BRAHE (and a big crater after himself), and gave the names of COPERNICUS and ARISTARCHUS to smaller ones. He experimented with falling bodies, intending to refute GALILEO and show that the Earth was at rest. His experiments, however, confirmed Galileo's concept of uniformly accelerated motion. He made general astronomical observations—of sunspots, Jupiter and Saturn, atmospheric refraction, and the positions of the stars. His observation in 1650 that Mizar was a double star was the first discovery of such a star with a telescope. He discovered Venus' ashen light phenomenon.

Richard of Wallingford (1291/2–1336(?))

Born in Wallingford, Oxfordshire, England, became abbot of St Albans, went to Avignon to have his appointment confirmed by the Pope, and contracted leprosy (or perhaps syphilis, scrofula or tuberculosis), dying young. He made and described an astronomical clock and an elaborate equitorium called Albion, a sort of analog computer that could make Ptolemaic calculations of lunar, solar and planetary positions, including eclipse predictions.

Richer, Jean (1630–96)

Born in France, became an 'astronomer' of the Académie Royal des Sciences. Carried out missions for the Académie, measuring the heights of the tides at La Rochelle at the equinoxes, and on a trip to Canada tested two clocks made by HUYGENS (they stopped, to Huygens' chagrin). In 1671 he went to Cayenne, French Guyana, as part of a campaign to measure the parallax of Mars and to examine the periods of pendulums at different points on his travels so as to determine the Earth's gravity. NEWTON and Huygens used the data to determine the shape of the Earth.

Rigel

The star β Orionis. At apparent magnitude 0.18 it is the seventh brightest star in the sky, and though designated β is actually the brightest star in Orion. Betelgeuse (α Orionis), now an irregular variable, may have been the brighter star when the Bayer letters were allocated in 1603.

Rigel ('Left Leg of the Giant') is a blue-white supergiant of spectral type B8Ia. With an absolute magnitude of -6.7 it is the most intrinsically luminous star known. It is an α Cygni-type pulsating variable, with a period of 2.07 days, magnitude range approximately 0.0–0.3. It has a faint companion which is itself a spectroscopic binary, separated from the primary by $9.5''$; the orbital period is not measurable. The system is 770 light-years distant, with a parallax of $0.004''$.

Right Ascension (RA)

The angle between the hour circles passing through the vernal equinox and a celestial body, measured eastwards (i.e. anti-clockwise) from the vernal equinox and expressed in time units (hours, minutes, and seconds) where 24 h is equivalent to 360°. In other words, it is the angle between the vernal equinox and a point on the celestial equator such that the angle between the vernal equinox, this point and a star is a right angle. The position of a star is normally expressed in terms of right ascension and declination.

See also: great circle, declination, hour angle.

Rille

A long narrow depression on the Moon's surface. There are several types. *Linear rilles* (or *straight rilles*), *forked rilles* and *arcuate rilles* are mostly graben—flat-bottomed strips of land that have collapsed between a pair of parallel fault lines. As their names imply, they may be straight or arc-shaped, and are often associated with large impact features. Examples are those named Rimae Mersenius and Rimae Hippalus, on opposite sides of Mare Humorum (rima is the term used in naming this type of feature). Different in origin are *sinuous rilles*. These are long, steep-sided channels, sometimes discontinuous, that wind their way across the floors of the lunar maria. They are in fact collapsed lava tubes, similar to those found on Earth. The surface of a narrow lava flow can solidify while lava beneath is still flowing, so that when the flow ceases an empty tube is left. A sinuous rille is produced when all or part of the roof of the tube collapses. An example of a lunar sinuous rille is the Hadley Rille, visited by the crew of Apollo 15. Sinuous rilles have also been identified on Venus and Mars. Some features on Uranus's satellite Ariel strongly resemble sinuous rilles, and may have a similar origin in a 'cryovolcanic' process in which melted ices can behave as lava.

Ring Nebula (M57, NGC 6720)

A planetary nebula in the constellation Lyra, position RA 18^{h} 53.6^{m}, dec. $+33^{\circ}$ $02'$. It is ninth magnitude and measures $70''$ by $150''$; the central star is only fifteenth magnitude. Its telescopic appearance resembles a smoke-ring.

Ritchey, George Willis (1864–1945)

At first a furniture-maker and woodworker, became an instrument-maker and especially an optician when he obtained part-time work at the observatory of the University of Cincinnati. Met GEORGE ELLERY HALE in Chicago and volunteered to assist him, preparing photographic plates, learning to use the camera to photograph stars and nebulae. Became a full time optician and supervisor of the instrument shop at Yerkes Observatory and made its 40 in refracting telescope work properly. He built the 24 in *Ritchey reflecting telescope* with which he discovered the expanding nebulosity around Nova Persei 1901. He also built the horizontal solar telescope, and the Snow horizontal telescope that replaced it. Ritchey followed Hale to the Mount Wilson Observatory, and made the 60 in and 100 in mirrors for the large Californian telescopes. He discovered a nova in a spiral galaxy, NGC 6946, showing the distances of galaxies as 'island universes'. Hale fell out with Ritchey and fired him. Ritchey went to live in France, where he implemented the design of the *Ritchey–Chrétien telescope*, a Cassegrain variant with paraboloidal concave primary mirror and ellipsoidal secondary mirror, and a curved focal plane (like the Anglo-Australian Telescope). He returned to the United States, and began to build a 40 inch Ritchey–Chrétien telescope for the US Naval Observatory in Washington, DC, but when he dropped the mirror he had been working on, the project lost confidence in him, and Ritchey retired.

Rittenhouse, David (1732–96) and Rittenhouse, Benjamin (1740–1825)

David was an instrument-maker and astronomer, born in Paper Mill Run, PA, self-taught, as a young man he made clocks and telescopes, introduced the use of spider's webs as cross-hairs in transit telescopes and made orreries to show planetary motions. He used his own instruments for astronomy. He worked to survey the MASON and DIXON line and taught astronomy at the University of Pennsylvania. He became a statesman, and was director of the US Mint. Benjamin, his brother, born in Norriton, was a craftsman, who made decorated compasses and clocks.

Robinson, Thomas Romney (1792–1882)

Irish astronomer, was director of the Armagh Observatory for 59 years (possibly a world record for an observatory director). Concentrated on determining star positions with newly installed meridian and transit telescopes. For the observatory Robinson procured from THOMAS GRUBB, the instrument-maker and founder of the telescope building company that bore his name, a 15 in diameter reflector. This was the first large Cassegrain telescope built in Britain, and the first large reflecting telescope to be mounted equatorially with a clock drive. It had a novel, lever-support system to maintain the shape of the speculum primary mirror against flexure due to gravity as the mirror changed attitude. This design for the mirror cell was later used for LORD ROSSE'S six foot reflector and for the Great Southern Telescope at Melbourne, whose construction Robinson also oversaw, and for a century of later Grubb-Parsons telescopes. Robinson observed with the 'Leviathan of Parsonstown'. The duties of the observatory included meteorology and Robinson invented the cup-anemometer to measure wind speed.

Roche Limit

The minimum distance from a planet at which a satellite can resist being gravitationally disrupted by tidal forces. It is given by $2.456R(\rho_p/\rho_s)^{1/3}$, where R is the planet's radius, and ρ_p and ρ_s are the densities of the planet and the satellite. This expression (without the density term) was derived in 1849 by Édouard Roche, and played a part in theories of the formation of Saturn's rings. Material within the Roche limit would be prevented from accreting into a larger body, while the break-up of a satellite that ventured inside the Roche limit would perhaps give rise to a ring system. The Roche limit as defined above applies to a fluid satellite—a hypothetical body of zero tensile strength—whereas real satellites are of course solid objects with a degree of structural integrity, able to offer some resistance to tidal disruption. Small satellites can in theory exist within the Roche limits for their bulk densities. However, it is not clear how many do, for the densities of the innermost satellites of the giant planets are mostly undetermined. Larger satellites, though, would be broken up within their Roche limit. If this happened, continued collisions between the resulting fragments, which would occupy similar orbits, would gradually produce progressively smaller and more numerous objects, and would thus create a ring system.

Roche Lobe

Within the region surrounding the components of a binary system there are two competing gravity fields. The Roche lobe, named after the French mathematician Édouard Roche (1820–1883), is the volume of space within which any matter is controlled by the gravity field of a single star. It is said to be bound by an 'equipotential surface' in which the gravitational force exerted by the star is equal at all points.

The Roche lobes of each component of a binary system, which in isolation would be spheroidal, are drawn out into cone-like extensions meeting at a point between the two stars known as the *Lagrangian point*, where the gravitational attractions of the two components are exactly equal. The position of this point along the line joining the centres of the two stars depends upon their relative masses. If one of the component stars expands to fill its Roche lobe, mass transfer will occur through the Lagrangian point towards the other star.

See also: binary system.

Roche, Édouard Albert (1820–83)

French astronomer and mathematician, *fl.* Montpellier, who studied the attractive force of rotating fluid bodies and discovered the *Roche limit*, the closest that a satellite can approach its planet and survive the stresses introduced when the nearer side tries to orbit faster than the further side. Empirically this closest distance is about 2.5 times the radius of the planet. Saturn's rings lie inside the Roche limit of Saturn. *Roche lobes* are the surfaces that define zones in a double-star system such that a test particle placed inside one of the surfaces will tend to gravitate towards the star near its center. If the star grows bigger than the zone in which it lies, it will expel material from its surface, possibly towards its companion star.

Rockets in Astronomy

Prior to the launch of the first satellite, Sputnik 1, in 1957, the only way to place scientific instruments above the atmosphere was to launch them on board rockets. In the following four decades, suborbital sounding rockets have continued to play a major role in improving our knowledge of the Earth, geospace and the universe as a whole.

Sounding rockets take their name from the nautical term 'to sound', which means to take measurements. The rockets consist of one or more stages, each with its own solid-fuel rocket motor, and a payload. They follow a parabolic trajectory, with less than 30 min of flight time. Following the launch, as the rocket motor uses its fuel, it separates from the vehicle and falls back to Earth. The payload continues into space and, once the experiment is completed, it re-enters the atmosphere. A parachute is deployed to bring the payload gently back to Earth for retrieval, a procedure that results in significant savings because all or part of the experiment can be refurbished and flown again.

The idea of using rockets to probe the upper atmosphere dates back to the 1930s, when ROBERT GODDARD proposed sending up small payloads that would parachute back to the ground from heights of up to 80 km (50 miles). Unfortunately, Goddard's plans were dashed by a lack of government interest and a shortage of funding.

As a result, rocket technology only became available for scientific research after American armed forces captured German V-2 missile factories at the end of the Second World War. Dozens of missiles and spare parts, along with blueprints and many of the key rocket designers (including WERNHER VON BRAUN), were shipped back to the United States and used to found the nation's missile program.

Between 1946 and 1951, 69 V-2s were launched from the US Army's White Sands Missile Range in New Mexico, reaching altitudes up to 185 km (116 miles). As the supply of captured missiles dwindled, a number of new rocket designs were introduced. These included the Aerobee, which was developed under the direction of space scientist JAMES VAN ALLEN from the Johns Hopkins University's Applied Physics Laboratory. Van Allen's main interest in using such vehicles was to observe cosmic rays before they struck the upper atmosphere.

Meanwhile, German engineers were also helping the Russians to build and fly their own V-2 rockets. These and their successors were launched from Kapustin Yar between 1947 and 1987. The rocket flights for atmospheric sounding were supervised by Soviet Academician A Blagonravov. The most used vehicle during the 1950s was a modified V-2, known as the R-1, which flew in five different versions.

A major impetus for rocket development and research on both sides of the Iron Curtain during the 1950s was the announcement that the 18 month period from 1 July 1957 to 31 December 1958 would be declared as International Geophysical Year (IGY). This would coincide with an expected peak in sunspot activity as well as several eclipses.

Almost 300 suborbital rocket launches were undertaken by the United States during this period, with another 175 sent up by the Soviet Union. Other countries that participated in IGY sounding rocket programmes included Australia, Canada, France, Japan and Great Britain. These were mainly designed to investigate the properties of the upper atmosphere, particularly the ionosphere.

Despite their short duration, these and subsequent suborbital flights made a number of scientific breakthroughs. The key to their success was the rocket's capability to lift detectors above the atmosphere which absorbed much of the cosmic radiation.

Attempts to study the universe at ultraviolet wavelengths from balloons during the 1920s were largely unsuccessful, since the Earth's ozone layer absorbs most of the incoming ultraviolet radiation. The first detection of ultraviolet radiation from the Sun had to wait until a spectrometer was carried to high altitude by a captured V-2 rocket in 1946. This was followed during the late 1950s by the first ultraviolet observations of stars from rockets carrying instruments with pointing capability. The breakthrough was achieved by Don Morton and Lyman Spitzer of Princeton University. Despite the failure of the rocket's parachute, their instrument survived to provide ultraviolet spectra for two stars in the constellation of Scorpius.

Also in 1946, T R Burnight from the US Naval Research Laboratory (NRL) reported fogging on a piece of photographic film carried aloft by a V-2. He claimed that the effect was caused by solar x-rays, but the cause of the blackening was questioned by other scientists. The first undisputed discovery of x-rays from the Sun had to wait until another NRL experiment, provided by HERBERT FRIEDMAN, flew on a modified V-2 rocket from White Sands in 1949. The experiment used a number of geiger counters to detect the radiation and provide basic directional information.

Then, on 18 June 1962, an Air Force experiment to search for x-rays from the Moon turned up a surprise. Three proportional counters on an Aerobee suborbital rocket found an x-ray source beyond the solar system in the constellation of Scorpius. The researchers, led by Italian physicist RICCARDO GIACCONI, called the discovery SCORPIUS X-1. Further celestial x-ray sources were discovered over the next few years by rocket-launched experiments.

INFRARED ASTRONOMY also gained an early boost from instruments on American suborbital rockets, this time provided by the US Air Force Cambridge Research Laboratories (later renamed the Air Force Geophysics Laboratory). Project HISTAR was prompted by the USAF's desire not to confuse the heat signature of an incoming enemy missile with the infrared emission from harmless astronomical sources. Accordingly, the Air Force launched a 16.5 cm (6.5 in) telescope, cooled by liquid helium, on a series of nine rockets, seven from White Sands

between April and December 1972, and two more from Australia in 1974. During some 30 min of accumulated observing time, more than 2000 cosmic infrared sources were detected at four wavelengths between 4 and 27 μm.

Although the limited size and mass of payload, together with the limited duration for observations, have reduced the number of such flights carried out in recent years, sounding rockets still offer a number of benefits. First, they are low cost and offer a launch flexibility not available with larger launch vehicles. They also provide the only means of making *in situ* measurements at heights between the maximum altitudes for balloons (about 48 km or 30 miles) and the minimum altitude for satellites (160 km or 100 miles).

Sounding rocket experiments provide a variety of information. This includes studies of the chemical composition and physical processes taking place in the atmosphere; measurement of the natural radiation surrounding the Earth; and data on the Sun, stars, galaxies and many other astronomical phenomena.

In addition, sounding rockets provide a reasonably economical means of conducting engineering tests for instruments and devices used on satellites and other spacecraft prior to their use in more expensive activities. Their low cost and short mission lead time mean that they are valuable scientific research tools for undergraduate and graduate students.

Although some countries, such as the UK, have phased out sounding rocket programs altogether, these launch vehicles are still widely used in the United States, Europe and Japan. NASA currently uses 15 different sounding rockets and launches about 30 such rockets each year. The launchers come in a variety of sizes from the single-stage Super Arcas, which stands 3 m (7 ft) tall, to the 20 m (65 ft) tall, four-stage Black Brant XII. These rockets can carry payloads of various weights to altitudes from 48 km (30 miles) to more than 1287 km (800 miles).

NASA sounding rockets are launched routinely from Wallops Island in Virginia, White Sands Missile Range in New Mexico and Poker Flat Research Range in Alaska, as well as sites in Canada, Norway and Sweden. They can also be launched from temporary launch ranges. In the past, NASA launch programs have been conducted from Peru, Puerto Rico, Brazil, Greenland, Australia and an aircraft carrier in the Pacific Ocean.

The Japanese space agency, ISAS, has also been building and launching sounding rockets for more than 30 yr. Many of these have been dedicated to astrophysical observations, upper atmosphere exploration, space plasma physics and other for scientific research. The main rockets used are the small MT-135, which is used primarily for middle atmosphere research, e.g. ozone layer depletion, the medium-range S-310 and the powerful S-520 which is capable of launching 100 kg of payload above 300 km (190 miles). These are usually launched from Kagoshima Space Centre on Kyushu island. Launch campaigns abroad with these sounding rockets have been made in Antarctica and at Andoya, Norway, for the *in situ* measurement of auroras.

Andoya Rocket Range (ARR) in the Svalbard archipelago is the world's northernmost permanent launch facility for sounding rockets. It provides favorable conditions for studying the ionosphere, the dayside aurora and processes in the magnetospheric boundary layer. Since 1972, ARR has been supported by several EUROPEAN SPACE AGENCY (ESA) member states. In return, the range facilities are available to the ESA member states on a marginal cost basis. By the beginning of 2000, the range had conducted 698 rocket launches.

Rooke, Lawrence (1622–62)

Born in Deptford, near London, became professor of astronomy and of geometry at Gresham College, London. Observed the satellites of Jupiter and made telescopic observations of lunar eclipses to determine longitude. But, more practical than many enthusiasts for these methods, he realized that they were too difficult to observe at sea, and could be used only to establish the longitude of cities and harbors. He proposed instead that a good lunar theory might provide an astronomical means to determine longitude at sea.

ROSAT (Röntgen Satellite)

The German–US–UK x-ray observatory ROSAT was launched into a 550 km circular orbit in June 1990. It carried two imaging telescopes operating in the soft x-ray (0.1–2.4 keV) and extreme UV (EUV) (006–0.2 keV) ranges. The x-ray telescope consisted of four nested Wolter type-I mirrors. The manufacturing of the x-ray mirrors — the largest and most accurate ones at that time — pioneered the use of Zerodur (a ceramic with zero thermal expansion) and an extremely low surface roughness (0.25 nm rms). In the telescope's focus were two position sensitive proportional counters (PSPC, 20 arcsec) and one high resolution imager (HRI, 5 arcsec). The EUV telescope consisted of three nested Wolter–Schwarzschild mirrors and two channel plate detectors (3 arcmin). The satellite and the x-ray telescope was designed, built and operated by Germany. NASA provided the Delta launch and the high resolution imager while the UK built and operated the EUV telescope. The prime ROSAT data centers were and are at the Max Planck Institute for Extraterrestrial Physics in Garching (x-rays) and at the University of Leicester (EUV) with mirror sites at the Goddard Space Flight Center and other scientific institutions.

ROSAT performed the first all-sky surveys with imaging x-ray and EUV telescopes leading to the discovery of 125 000 x-ray and 479 EUV sources. In addition the diffuse galactic x-ray emission was mapped with unprecedented angular resolution ($\leq$ 1 arcmin). Most of the mission time was devoted to pointed observations at selected targets. In total 4580 PSPC and 4482 HRI fields were covered with observation times between ~ 2000 s and ~ 1 Ms. Seven hundred scientists ('Principal Investigators') from 24 countries were involved in these pointed observations. The total number of ROSAT-based publications is 4787, with 54.9% in refereed journals (August 2001). All ROSAT data are calibrated and archived and are available through

http://wave.xray.mpe.mpg.de/rosat/catalogues

A large number of discoveries were made using both the all-sky survey and the pointed observations of ROSAT:

- x-ray shadows cast by cool interstellar clouds on the soft x-ray background in the Galaxy and nearby galaxies;
- x-rays and EUV light from the sunlit side of the Moon;
- x-rays from brown dwarfs;
- x-rays from T Tauri stars located at large distance from their birthplaces;
- underluminosity of single white dwarfs in x-rays and EUV, due to metals in their atmospheres;
- blackbody-like emission from intermediate polars;
- supersoft x-ray sources — nuclear burning on accreting white dwarfs;
- x-ray emission from the photospheres of single neutron stars;
- x-ray emission from millisecond pulsars;
- x-ray pulsations of the enigmatic γ ray source Geminga and its identification as a neutron star;
- x-ray and EUV emission from comets (e.g. Hyakutake, Levi);
- soft x-ray emission from the shock wave of SN 1987A;
- x-ray emitting explosion fragments in the Vela Supernova remnant;
- strong and highly variable x-ray emission from narrow line Seyfert galaxies;
- 80% of the cosmic x-ray background resolved into discrete source, mostly active galactic nuclei (AGN);
- superluminous flares at the centers of normal galaxies indicating episodic accretion onto supermassive black holes;
- x-ray diagnostics of merging clusters of galaxies;
- interaction between AGN jets and the intracluster medium in clusters of galaxies;
- measurement of the large-scale structure up to scales of ~ 700 Mpc using large samples of x-ray detected clusters of galaxies.

ROSAT was switched off in February 1999 after 8½ years of successful operation.

Rosetta

The International Rosetta Mission was approved in November 1993 by ESA's Science Programme Committee (SPC) as the Planetary Cornerstone Mission in ESA's long-term program Horizon 2000. The mission goal is a rendezvous with comet 46P/Wirtanen. A subsidiary aim is the study of two asteroids during close fly-bys en route to the comet.

Background

Our knowledge of small solar-system bodies, the COMETS and ASTEROIDS, has improved dramatically over the last 20 yr. The major milestones were undoubtedly the first fly-bys of COMET HALLEY by the GIOTTO, VEGA, SAKIGAKE and SUISEI probes in 1986, the Giotto Extended Mission to comet Grigg–Skjellerup in July 1992, the first near encounters with main-belt asteroids Gaspra and Ida by the GALILEO spacecraft on its way to Jupiter, the encounters with Braille by Deep Space 1 and with near-Earth object Mathilde by the NEAR spacecraft, and finally NEAR's rendezvous with EROS in February 2000. During the same period, telescopic observations performed on the ground or in Earth orbit have greatly expanded and diversified. They constitute the basis for understanding small bodies as a population, since we can now compare observations of a large variety of objects and can undertake investigations of the variability of cometary activity. In particular, the outstanding opportunities to observe two bright comets, Hyakutake and Hale–Bopp in 1995 and 1996, provided new insights into cometary composition from ground-based observations.

Systematic observations in the visible spectrum are being performed for short-period comets as well as main-belt and near-Earth asteroids. It is now possible to observe cometary nuclei even at large heliocentric distances from the ground and with the Hubble Space Telescope. Furthermore, small bodies have now been studied systematically at all wavelengths from the ultraviolet, via the infrared to microwave and radio wavelengths. Here the International Ultraviolet Explorer (IUE) and ESA's Infrared Space Observatory (ISO) played, among others, an important role.

From this wealth of new information, it is becoming apparent that asteroids and comets constitute an almost continuous suite of progressively less evolved objects, reflecting the radial gradient in the swarm of planetesimals during the formation of the solar system. Indeed, the outermost asteroids exhibit spectral similarities to the bare cometary nuclei observed far from the Sun. A better understanding of the relationship between asteroids, comets and PLANETESIMALS throughout the solar nebula is an essential step in unravelling the first stages of the formation of the solar system.

Cometary material has been submitted to the lowest level of processing since its condensation from the protosolar nebula. It is considered likely that pre-solar grains may have been preserved in comets. As such, cometary material should constitute a unique repository of information on the sources that contributed to the protosolar nebula, as well as on the condensation processes that resulted in the formation first of planetesimals and then of larger planetary bodies. While tantalizing results have been obtained *in situ* from cometary grains and from interplanetary dust particles collected on Earth, the latter cannot be considered as fully representative, in particular in terms of their organic and volatile complement.

Two solutions to the problem of obtaining unaltered material can be considered: returning to Earth a sample of a COMETARY NUCLEUS (the original Rosetta concept of a comet-nucleus sample-return mission) or staying close to the comet and performing comprehensive *in situ* analyses of material from the surface and the coma.

The first approach had the undisputed advantage of bringing the full range of analytical techniques that are, or will be, available in the laboratory to bear on investigations of the sample material. Limiting thermal and mechanical stresses to acceptable levels during cruise and recovery, and even defining these acceptable levels, represented a significant scientific and technological challenge. The approach of a rendezvous mission with a suite of high-resolution remote sensing instruments and very sensitive *in situ* analytical investigations results in a less complex and cheaper mission and guarantees by design minimal perturbations of the cometary material, as analyses are performed *in situ*, at low temperatures and in a microgravity environment. It also provides the opportunity of observing at close range the onset and development of cometary activity, which results in the spectacular displays that have captured the imagination of humanity over the centuries.

Direct evidence on cometary volatiles is particularly difficult to obtain, as species observable from Earth and even during the Halley fly-bys result from physicochemical processes such as sublimation, interaction with solar radiation and the solar wind. The currently available information on cometary material gained from *in situ* studies and ground-based observations demonstrates the low level of evolution of cometary material. The latter's tremendous potential for providing information on the constituents and early evolution of the solar nebula has yet to be exploited.

Studying cometary material represents a major challenge, owing to the very characteristics that make it a unique repository of information about the formation of the solar system, namely its high content of volatiles and organic material.

A fundamental question that has to be addressed by the mission is, to what extent can the material accessible to analyses be considered as representative of the bulk material constituting the comet and of the early nebular condensates that constituted the cometesimal 4.57×10^9 yr ago? This representativity issue has to be addressed by first determining the global characteristics of the nucleus (mass, density, state of rotation), which can provide clues

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

concerning vertical gradients, and hence the relationship between the outer layers and underlying material.

The dust and gas activity observed around comets, as well as its rapid response to insolation, guarantees the presence of volatiles at or very close to the surface in active areas. Analyzing material from these areas will therefore provide information on both the volatile and the refractory constituents of a cometary nucleus. The selection of a proper site for surface science investigations should be relatively straightforward, given the extensive remote sensing observation phase and the advanced instrumentation, which covers a broad range of wavelengths, being provided on the Rosetta orbiter. The surface science sites can be monitored during surface activities as well as during a large fraction of the activity cycle, which should bring to light clues concerning the compositional heterogeneity of active regions.

The dust-emission processes are induced by very low-density gas outflows and should preserve the fragile texture of cometary grains. These grains can be collected at low velocities (a few tens of meters per second) by the spacecraft after short travel times (of the order of minutes), which will minimize alterations induced by the interaction with solar radiation. Similarly, gas analyzed in jets or very close to the surface should yield information on the volatile content of cometary material in each source region.

The Rosetta mission will study the nucleus of comet 46P/Wirtanen and its environment in great detail for a period of nearly two years, the near-nucleus phase starting at a heliocentric distance of about 3.25 AU, from the onset of activity through to perihelion, close to 1 AU. On its long journey to the comet, the spacecraft will pass close to two asteroids, 4979 Otawara and 140 Siwa.

Some questions to be answered

Just as the Rosetta Stone was the key that unlocked the meaning of Egyptian hieroglyphs, so the Rosetta spacecraft (figure 1) is intended to decipher the meaning of comets and their role in the origin and history of the solar system. Here are a few of the main puzzles.

- *What is the bulk density of a comet?* Guesses about the density of cometary material vary widely, and only an orbiting spacecraft can give exact measurements of the comet's volume and mass.
- *Is a comet a dirty snowball or an icy dirtball?* In other words, is it made of ices contaminated with mineral and tarry dust, or is it a consolidation of dust coated with ices?
- *Why is the nucleus of a comet so dark?* Giotto established that Halley's nucleus is like brownish-black velvet, absorbing 96% of the sunlight falling on it. Is the color due to a surface deposit of tarry dust, or is the interior dark too?
- *Why are small regions of a comet highly active when most of its surface is not?* Multiple jets of dust seen emanating from Halley's comet, and spectacularly from comet Hale–Bopp, imply that certain hot-spots differ physically or chemically from the rest of the comet's surface.

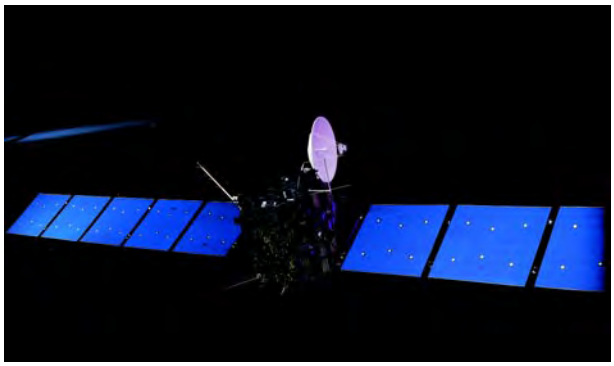

Figure 1. The Rosetta spacecraft.

- *Is a comet made as single piece, or does it consist of loosely joined blocks, as suggested by the Giotto images?* This relates to the questions of how comets are built, and why they break up into smaller fragments, as seen spectacularly with comet Shoemaker–Levy 9 which hit Jupiter in 1994.
- *Does a dying comet evaporate and disappear, or does it simply exhaust the stocks of ice that drive the emissions of gas and dust from an active comet?* If the latter answer is correct, dead comets persist long afterwards as dark, inactive masses of minerals and tar, and pose a lasting threat of collisions with the Earth.
- *What is a comet's exact composition?* Many ingredients are known, and the approximate abundances of the main constituents. Details coming from Rosetta will pin down (1) how comets were fashioned from similar constituents of interstellar dust and (2) how comets contributed to building the planets, including the Earth, and stocking their atmospheres.
- *Is the tarry, carbon-rich material in comets a jumble of every kind of chemical that inorganic processes can make from carbon, nitrogen, oxygen and hydrogen, or does it contain special compounds?* This is relevant to assessing the role of comets in the origin of life on the Earth.

Scientific objectives

The prime scientific objective of the mission as defined by the Rosetta Science Study Team is to study the origin of comets, the relationship between cometary and interstellar material and its implications with regard to the origin of the solar system. The measurements to be made in support of this objective are as follows:

- the global characterization of the nucleus, determination of dynamic properties, surface morphology and composition;
- the determination of the chemical, mineralogical and isotopic compositions of volatiles and refractories in a cometary nucleus;
- the determination of the physical properties and interrelation of volatiles and refractories in a cometary nucleus;

Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

- the study of the development of cometary activity and the processes in the surface layer of the nucleus and the inner coma (dust–gas interaction);
- the global characterization of asteroids, including determination of dynamic properties, surface morphology and composition.

Comet 46P/Wirtanen

Comet 46P/Wirtanen ($P = 5.5$ yr), a Jupiter family comet, has been chosen as the prime target of the International Rosetta Mission. Jupiter family comets not only present a large group of the short-period comets in the solar system but also in principle are observable along their entire orbit. Thus, they are excellently suited to serve as targets for a complete description of the evolution of a comet along its orbit. Comet 46P/Wirtanen was discovered by Carl A Wirtanen at Lick Observatory on 15 January 1948 and described as a diffuse 17 mag object with a central condensation. Two close approaches to Jupiter in 1972 (0.28 AU) and 1984 (0.47 AU) changed the orbit from an initial perihelion distance of 1.63 AU and a period $P = 6.71$ yr to a perihelion distance of 1.06 AU and a period $P = 5.46$ yr.

Except in 1980, the comet was observed during all its apparitions. After the reduction of its perihelion distance, 46P/Wirtanen had come into reach of the visual observers and a first light curve of the observations in 1986 and 1991 was compiled. The coordinated observational campaign during its latest apparition in 1996–7 made this object one of the best-monitored comets. Some basic parameters of the nucleus could be derived and the evolution of its activity along the same part of the orbit that will be covered by Rosetta was closely monitored.

Assuming a geometric albedo of 0.04 a radius of about 600 m was derived with an upper limit of 700 m. Its gas production rate at perihelion is about 10^{28} molecules s^{-1}, about a factor of 100 less than 1P/Halley, which, however, is fairly active for such a small nucleus.

Scientific payload

In February 1996, ESA's SPC endorsed the Rosetta Orbiter Payload, and originally two Surface Science Packages—Champollion to be provided by NASA–JPL/CNES and Roland to be provided by a European consortium led by MPI and DLR from Germany—and five Interdisciplinary Scientists. Programmatic difficulties led to the withdrawal of NASA from Champollion in September 1996. CNES has joined the original Roland consortium to provide a single European Lander.

The Orbiter Payload has unprecedented capabilities to study the composition of both the volatile and refractory material released by the cometary nucleus with very high resolution. The remote sensing suite of instruments (see table 1) will allow for a characterization of the nucleus surface in a wide wavelength range from UV to mm with high resolution, e.g. the narrow-angle camera of OSIRIS will achieve from close orbits a resolution on the nucleus surface of better than 4 cm.

To complement these instruments and to provide for a proper monitoring of the comet environment and its interaction with the solar wind, a dust flux analyzer and a plasma instrument package have been selected.

Rosetta Lander payload

The Lander science (see table 2) will focus on the *in situ* study of the composition and structure of the nucleus material. Measurement goals include the determination of the elemental, molecular, mineralogical and isotopic composition of the cometary surface and subsurface material. Highest priority is given to the elemental and molecular determinations, as it is believed that some mineralogical and isotopic measurements can be carried out adequately by Orbiter science investigations. In addition properties such as near-surface strength, density, texture, porosity, ice phases and thermal properties will be derived. Texture characterization will include microscopic studies of individual grains.

CONSERT, with hardware on both the Lander and the Orbiter, will try to reveal the coarse structure of the nucleus through radio sounding.

Interdisciplinary Scientists

Five Interdisciplinary Scientists were nominated in support of the mission:

- M Fulchignoni, DESPA, Observatoire de Paris, France;
- M Fulle, Trieste Astronomical Observatory, Italy;
- E Grün, MPI für Kernphysik, Heidelberg, Germany;
- R Schulz, MPAe, Lindau, Germany, now ESA Space Science Department;
- P Weissman, NASA–JPL, Pasadena, CA, USA.

Mission overview

Rosetta will by launched in January 2003 by an Ariane 5 from Kourou. To gain enough orbital energy to reach its target, one Mars and two Earth gravity assists will be required (see table 3). The long mission duration required the introduction of extended hibernation periods. The mission can be subdivided into several distinct phases.

Table 3. Major mission events.

Event	Nominal date
Launch	15 January 2003
Mars gravity assist	26 August 2005
Earth gravity assist 1	26 November 2005
Otawara fly-by	11 July 2006
Earth gravity assist 2	26 November 2007
Siwa fly-by	25 July 2008
Rendezvous maneuver	24 August 2011
Start near nucleus operations at 3.25 AU (from Sun)	22 August 2012
Perihelion passage (end of mission)	10 July 2013

Table 1. Individual instruments on the Rosetta Orbiter.

Short name	Objective	Principal investigator
Remote sensing		
OSIRIS	Multicolor imaging (narrow- and wide-angle camera)	H U Keller, MPAe, Katlenburg-Lindau, Germany
ALICE	UV spectroscopy (70 nm–205 nm)	A Stern, SWRI, Boulder, CO, USA
VIRTIS	Visible and IR mapping spectroscopy (0.25 μm–5 μm)	A Coradini, IAS–CNR, Rome, Italy
MIRO	Microwave spectroscopy (1.3 mm and 0.5 mm)	S Gulkis, NASA–JPL, Pasadena, CA, USA
Composition analysis		
ROSINA	Neutral gas and ion mass spectroscopy; double focusing, 12–200 AMU, $M/\Delta M \sim 3000$ Time of flight, 12–350 AMU, $M/\Delta M \sim 1500$ including neutral dynamics monitor	H Balsiger, University of Bern, Switzerland
COSIMA	Dust mass spectrometer (SIMS, $M/\Delta M \sim 2000$)	J Kissel, MPE Garching, Germany
MIDAS	Grain morphology (atomic force microscope, nm resolution)	W Riedler, Institute for Space Research, Graz, Austria
Nucleus large-scale structure		
CONSERT	Radio sounding, nucleus tomography	W Kofman, CEPHAH, Grenoble, France
Dust flux, dust mass distribution		
GIADA	Dust velocity and impact momentum measurement, contamination monitor	L Colangeli, Osservatorio Di Capodimonte, Naples, Italy
Comet plasma environment, solar wind interaction		
RPC	Langmuir probe	R Boström, Swedish Institute of Space Physics, Uppsala, Sweden
	Ion and electron sensor	J Burch, SRI, San Antonio, TX, USA
	Flux gate magnetometer	K-H Glassmeier, TU Braunschweig, Germany
	Ion composition analyzer	R Lundin, Swedish Institute of Space Physics, Kiruna, Sweden
	Mutual impedance probe	J G Trotignon, LPCE/CNRS, Orleans, France
RSI	Radio science experiment	M Pätzold, University of Cologne, Germany

Table 2. The Lander payload.

APXS	α–p x-ray spectrometer	R Rieder, MPI Chemistry, Mainz, Germany
SD^2	Sampling and drilling device	A E Finzi, Politechnico Milano, Italy
COSAC	Evolved gas analyzer, elemental, molecular composition	H Rosenbauer, MPAe, Katlenburg-Lindau, Germany
MODULUS	Evolved gas analyzer, isotopic composition	I Wright, Open University, UK
ÇIVA	Panoramic camera, IR microscope	J P Bibring, IAS, Orsay, France
ROLIS	Descent camera	S Mottola, DLR Berlin, Germany
SESAME	Surface electrical and acoustic monitoring, dust impact monitor	D Möhlmann, DLR Cologne, Germany H Laakso, FMI, Finland I Apathy, KFKI, Hungary
MUPUS	Multipurpose sensor for surface and subsurface science	T Spohn, University of Münster, Germany
ROMAP	Roland magnetometer and plasma monitor	U Auster, TU Braunschweig, Germany I Apathy, KFKI, Hungary
CONSERT	Comet nucleus sounding	W Kofman, CEPHAG, Grenoble, France

The science mission phases

Otawara fly-by (July 2006)
Fly-by operations last from 3 months before to 1 month after the fly-by. Parallel to the daily tracking with orbit determination and corrections, the scientific payload is checked out. The aim is to pass the asteroid at a distance of about 1000 km on the Sunward side. The relative asteroid ephemeris will be determined with a cross track accuracy of 20 km by spacecraft optical navigation. The cameras and scientific payload will be pointing in the direction of the asteroid until after the fly-by.

Siwa fly-by (July 2008)
The operations are similar to the Otawara fly-by; however, the fly-by distance will be of the order of 2500 km to be commensurate with the spacecraft angular rate capabilities which are determined by the requirements of the Otawara fly-by, which occurs at a lower relative velocity.

Global mapping and close observation phase
The preliminary survey of the surface of the comet is known as global mapping. At least 80% of the surface subject to solar illumination is required to be mapped.

Even in the gravity field of a nucleus of very irregular shape, it will be possible to choose quite stable orbits that do not impact on the cometary nucleus. Polar orbits around the comet at a distance between 5 and 25 nucleus radii will be used for mapping the surface. The orbital period will be usually greater than the spin period; horizontal swaths will cover the nucleus surface as it is presented. The semimajor axis of the mapping orbit will be chosen as a function of comet gravity and spin rate, taking into account the following constraints:

- coverage without gaps;
- safety considerations (no impact on nucleus);
- volume of data for real-time transmission;
- maximum time to complete surface mapping;
- minimum resolution and viewing angle to surface normal;
- continuous communications with Earth.

In case of slowly rotating comets, it may be necessary to use more than one revolution in the same orbit or a second different orbit by means of plane change maneuvers.

Ideally all the Orbiter payload instruments are operating during this phase. The scientific data gathered by the whole payload is buffered in the on-board memory, before transmission to the ground station.

The nucleus shape and surface properties as well as kinematics and gravitational models will be derived using optical landmark observations. Based on the mapping and remote observation data, five areas will be selected for close observation.

At the end of the close observation phase, based on the collected data, a decision will be taken to which site the Surface Science Package (SSP) will be delivered.

Surface Science Package delivery phase
Surface Science Package delivery will be from an eccentric orbit (pericenter altitude as low as possible, e.g. 1 km) with a pericenter passage near the desired landing site. The time and direction of the SSP separation will be chosen such that the package arrives with minimum vertical and horizontal velocities relative to the local (rotating) surface. An ejection mechanism will separate the SSP from the spacecraft with a maximum relative velocity of up to 1.5 m s^{-1}.

After delivery of the SSP, the spacecraft will be injected into an orbit that is best suited to receive the data transmitted from the SSP and to relay them to the Earth.

Extended monitoring phase (through perihelion)
After the end of the activities related to the SSP, the spacecraft will spend at least 200 days in orbit in the vicinity of the comet until perihelion passage. The objective of this phase is to monitor the nucleus (active regions), dust and gas jets and to analyze gas, dust and plasma in the inner coma from the onset to peak activity. Orbits between 1 and 10 cometary radii are envisaged.

Orbital design will depend on safety considerations and scientific goals taking into account that the communication relay service has to be provided for the long-life SSP. Mission planning will depend on the results of previous observations, such as the activity pattern of the comet. Extended monitoring of different regions in the vicinity of the nucleus could be performed by successive hyperbolic fly-bys configuring petal-like trajectories.

Spacecraft overview and payload accommodation

The spacecraft design is driven by key features of this very complex and challenging mission:

- the fixed and fairly short launch window for comet 46P/Wirtanen—because of the launch capability required, even for Ariane 5 there exist only very few backup scenarios within a reasonable time frame;
- the long mission duration of 10.5 yr;
- the critical gravity assists at Mars and the Earth and the close asteroid fly-bys, where the spacecraft and the payload will be active;
- the wide variation of spacecraft–Earth–Sun cycles and distances, which poses challenges for the thermal design and require large solar arrays (approximately 64 m^2) with novel cells for low-intensity low-temperature operation;
- the long operations in close proximity to the comet surface—only a few comet nucleus radii away in an environment (dust and gas emitted from the nucleus) that will not be known in great detail during development.

The long round-trip times for light of up to 90 min require an autonomous spacecraft that in addition will be able to survive a long hibernation phase without any ground contact during the cruise.

Gerhard Schwehm

The payload is mounted on one spacecraft wall, which during the close comet phase will continuously be pointed towards the nucleus. All instruments are body mounted and the proper attitude is achieved by rotating the spacecraft with the high-gain antenna always pointing towards the Earth and the solar array pointing towards the Sun.

Résumé

A sophisticated payload such as the one to be flown on the Rosetta mission and especially the goal to deploy a Lander onto the nucleus surface for *in situ* investigations requires laboratory simulations of nucleus properties of which we have very little—and only indirect—knowledge.

To land the Lander and to anchor it into the nucleus surface requires basic knowledge of the material, its tensile strength, density and structure. The evidence for all of these parameters is still extremely tenuous. The presence of small-scale and possibly larger-scale active areas, such as the craters seen on Halley Multicolour Camera images of comet 1P/Halley, clearly indicates that there are differences in the near-surface properties. These in turn must be related to physical or chemical heterogeneities within the nucleus. However, from ground-based observations it is not possible to determine whether variations in activity stem from small-scale heterogeneity (such as variations in the thickness of the mantle) or from larger-scale variations of the volatile content of underlying porosity.

One of the main scientific objectives of the mission is the study of the physicochemical processes that are specific to comets. The increase in cometary activity as these bodies approach the Sun undoubtedly represents one of the most complex and fascinating processes to be observed in the solar system.

A full understanding of cometary activity involves inputs from a wide range of disciplines, including thermodynamics, phase equilibrium, gas–solid interactions, fluid dynamics, heterogeneous chemistry, photochemistry and plasma physics.

The mission will provide information on 'how a comet works' and will be crucial to our understanding of the early solar nebula and the evolution of the planetary system. The study of the chemical (isotopic) composition of the ices and the dust grains will provide us with information on the processes through which these elements formed and about prebiotic chemistry. It will answer the question what role comets played in the evolution of life on Earth.

Rosetta is a fascinating mission that will address many key questions about our origins: if we want to understand the origins of the solar system, we have to study comets.

Rosette Nebula (NGC 2237–39, 2246)

A complex emission nebula in the constellation Monoceros, position RA $06^{h}\ 30.3^{m}$, dec. $+05^{\circ}\ 03'$. It surrounds the star cluster NGC 2244, the stars of which energize its gas. Different parts of the nebula received separate NGC designations; the whole resembles a rosette or wreath.

Rosse, 3rd Earl of [William Parsons, Lord Rosse, Lord Oxmantown] (1800–67) and Rosse, 4th Earl of [Laurence Parsons, Lord Rosse, Lord Oxmantown] (1840–1908)

Irish astronomer and landowner, the 3rd Lord Rosse was educated at Trinity College, Dublin and Oxford as a mathematician. He became interested in astronomy and made at the family castle in Birr a 36 in reflector with the same design as William Herschel's (see HERSCEL FAMILY). Mapped the Moon, and observed nebulae with the intent to resolve them into stars. He developed the technology at Birr Castle to make speculum mirrors, using the estate's blacksmiths, labourers and materials (such as peat for the fuel for the furnaces). In 1842, he successfully cast a 72 in mirror for the 'Leviathan of Parsonstown', which stood as the largest telescope in the world at the time (1845–1917), slung between two massive walls aligned on the meridian. The telescope, restored to working order in 1998, was raised in elevation, and tracked for a small angle across the meridian, by a system of ropes and pulleys. The observer had access to the eyepiece from chairs mounted on the walls and was able to observe an object for at most an hour and a half. The potato famine in Ireland delayed the astronomical work of the telescope until 1848, from when it was used to view planets, satellites and nebulae. In over a dozen nebulae Lord Rosse, his son, his astronomical assistants and visiting observers (like J L E DREYER and THOMAS ROMNEY ROBINSON) were able to resolve spiral arms, indicating that they were more than just collections of gas—galaxies in fact. They went so far as conclude that 'no real nebulae seem to exist . . . all appeared to be clusters of stars'. Lord Rosse also realized that some elliptical and lenticular nebulae were edge-on spirals. Lord Rosse's drawings of the nebulae were strikingly accurate, although there was a curious lapse in the telescope's first record of M1, where a fanciful drawing with many radial 'legs' inspired the enduring name Crab Nebula. The 3rd Earl Rosse's son, Laurence, the 4th Earl Rosse, fitted both the 72 in and the 36 in telescopes with spectroscopes. His observations proved that some nebulae had bright-line spectra, including all the planetary nebulae, and others, including the Andromeda galaxy, were made up of stars. He also measured the temperature of the Moon by focusing its light onto a thermocouple, watching the temperature drop during an eclipse.

Rossi X-ray Timing Explorer (RXTE/Explorer 69)

NASA mission to study variations in x-ray emissions on time scales from microseconds to years. Named in honour of x-ray astronomy pioneer Bruno B Rossi, former Professor of Physics at Massachusetts Institute of Technology. Launched December 1995. Carries a Proportional Counter Array and High-Energy X-ray Timing Experiment to study compact objects in the energy range 2–200 KeV. Also has an All Sky Monitor which scans over 70% of the sky each orbit. Key feature is flexible operations through rapid pointing, high data rates and nearly continuous receipt of data. Discovered millisecond x-ray pulsars and high-frequency x-ray pulses from neutron stars in binary systems. (See EXPLORER.)

Rossi, Bruno Benedetto (1905–93)

Cosmic ray physicist, born in Venice, Rossi studied and worked in Italy until the Fascist regime dismissed him. He held positions in Europe and joined the Los Alamos Laboratory in New Mexico, to develop the atomic bomb. He became professor at MIT. He devised the *Rossi coincidence circuit*, which recorded the simultaneous occurrence of electric pulses in cosmic ray and other detectors to distinguish real events from noise. He investigated the nature of and energies of cosmic rays, and placed detectors in space for cosmic ray investigations, discovering with the Explorer X satellite in 1961 the magnetopause, the boundary containing the Earth's magnetic field. With RICCARDO GIACCONI he launched a rocket to detect cosmic x-rays (from the Moon), which discovered by chance, behind the Moon, the Scorpius X-1 x-ray source, the first discovered. An x-ray astronomy satellite, the Rossi X-ray Timing Explorer (RXTE), is named after him.

Rotation

The motion of a body about an axis; for example, the Earth rotates on its axis in a period of 23 h 56 min. All celestial bodies, such as planets, stars and galaxies, exhibit some degree of rotation.

See also: axis, orbit, revolution.

Royal Astronomical Society

The Royal Astronomical Society (RAS) represents professional astronomers and geophysicists in the UK. It was founded in 1820 as the Astronomical Society of London by John Herschel and 13 other well-known astronomers and scientists. The Society received the grant of a Royal Charter from King William IV in 1831. Its headquarters are in Piccadilly, London.

The Society's aims are 'the encouragement and promotion of astronomy and geophysics'. Its main functions are to publish the results of astronomical and geophysical research, to maintain as complete a library as possible in these subjects and to hold meetings, in London and elsewhere, at which astronomical and geophysical matters can be discussed.

The RAS is affiliated to the European Astronomical Society and to the European Geophysical Society. With the Geological Society, it has formed a Joint Association for Geophysics to promote geophysics.

The RAS library contains material for research in astronomy and geophysics as well as the histories of these sciences and of associated fields such as navigation. Collections of the Society's instruments are loaned to museums, universities and observatories throughout the UK.

The Society publishes research papers in two academic journals: *Monthly Notices of the Royal Astronomical Society* for astronomers and *Geophysical Journal International* for geophysicists. The Society's house publication, *Astronomy and Geophysics* carries reports of scientific meetings, papers on current topics, correspondence and book reviews.

Regular scientific discussion meetings are organized in London, while annual national astronomy meetings are held at different venues. The Society has a number of interactions with the Particle Physics and Astronomy Research Council (PPARC) and the Natural Environment Research Council (NERC). The Society awards the Michael Penston Astronomy Prize (formerly the RAS Astronomy Prize) and the RAS Blackwell Prize, and awards a number of medals for contributions to astronomy and geophysics.

Royal Astronomical Society of Canada

The Royal Astronomical Society of Canada, originally known as the Toronto Astronomical Club, was founded in 1868 by eight charter members. On 25 February 1890, in Toronto, it was incorporated with a constitution and bylaws. In 1903 it became known as the Royal Astronomical Society of Canada. Today, the Society has 23 affiliated centers from coast to coast, and a membership of close to 4000.

The Society produces several widely respected publications, including the *Journal of the Royal Astronomical Society of Canada*, the *Observer's Handbook*, the *Beginner's Observing Guide*, and the *Observer's Calendar*.

For further information see the publication *Looking Up* or the Society's website at http://www.rasc.ca.

Royal Observatory, Edinburgh

The Royal Observatory, Edinburgh (ROE) comprises the UK Astronomy Technology Centre (ATC) of the PARTICLE PHYSICS AND ASTRONOMY RESEARCH COUNCIL, and the University of Edinburgh's Institute for Astronomy.

The Institute for Astronomy is a research and teaching group within the university's Department of Physics and Astronomy. It is one of the UK's major centers of astronomical research, particularly involving cosmology, active galaxies and star formation.

The institute has a 0.5 m telescope and a 3.5 m spectrograph/solar telescope, infrared, reticon and CCD detectors, facilities for photography, photoelectric photometry, polarimetry and a CCD spectrograph.

The ATC is the UK's national center for the design and production of state-of-the-art astronomical technology. It includes an applied optics group which designs and builds instruments for both ground-based telescopes (UKIRT, GEMINI, ING) and space telescopes (FIRST, NGST). Other groups in the ATC deal with mechanics, electronics and software. Major technology research is undertaken into CCD detectors/cameras, infrared systems, submillimeter and cryogenics.

Particular research interests of the ATC astronomy group include star and planet formation, brown dwarfs and interacting galaxies. One of the main areas of study is the remnant dust disks around main sequence stars such as Vega.

The ROE manages UK telescope sites and data archive resources. It is the home of the Plate Library for the UK Schmidt telescope, which contains over 17 000 plates, and the SuperCOSMOS advanced photographic plate digitizing machine.

The ROE was founded in 1811 by a group of amateur and professional astronomers. Originally known as the Astronomical Institution of Edinburgh, it was renamed the Royal Observatory in 1822 after a visit to the city by King George IV. In 1834, the University of Edinburgh took over its administration on condition that the government would provide the salary for a professor who would hold the title of Astronomer Royal for Scotland. The link continued until 1995, when this honorary title was separated from the post of Director of the ROE.

Royal Observatory, Greenwich

The Royal Observatory at Greenwich, London, founded in 1675, is the location of the Airy Transit Telescope that defines the prime meridian of the world and is the home of the Harrison Chronometers. The Observatory was founded by Charles II with the ultimate purpose of providing an accurate star catalog and model of the Moon's motion, that enabled mariners to find their longitude. During the twentieth century the observatory became increasingly involved in astrophysics and the research arm, known as the Royal Greenwich Observatory, moved from the Greenwich site in the 1950s and was eventually closed in 1998. The Greenwich site is now a museum, visited by half a million visitors per year, containing clocks, astronomical instruments, including a 70 cm refractor and a planetarium. It is administratively part of the nearby National Maritime Museum. The buildings, including Flamsteed House designed by Christopher Wren, have been restored. The Observatory contains a public information group that answers public and media enquiries about modern astronomy. It will be the management center of the 2 m Faulkes telescope for public education, located in Hawaii and used by students in Hawaii and the UK.

For further information see http://www.rog.nmm.ac.uk/.

RR Lyrae Stars

RR Lyrae stars are members of a class of VARIABLE STAR whose variations in light, radius and temperature are known to be caused by self-sustained radial pulsations of giant A stars with masses between 0.5 and 0.8 solar masses, mean radii of 5 times the radius of the Sun and absolute magnitudes at mean light of $\langle M_V \rangle \sim +0.5$. The amplitudes of their light curves range between 0.2 and 1.8 magnitudes in B. Their periods range between 0.25 and 1.2 days.

Although early called 'short-period Cepheids' because the shapes of their light, color and radial velocity curves are so similar to those of the long-period classical Cepheids, it was soon realized that the two groups were in fact separate in other of their characteristics. They differ in their spatial distribution in the Galaxy. The long-period classical Cepheids are concentrated to the Galactic disk while the field RR Lyrae stars have an almost spherical distribution in Galactic latitude. Furthermore, most of the RR Lyraes have high space velocities relative to the local standard of rest, whereas the long-period classical Cepheids have the low space velocities characteristic of extreme population I stars (see STELLAR POPULATIONS).

By 1950 it had become evident that the two groups of variables are of different population types and are in different evolutionary states. Using the RR Lyrae stars of the extreme population II, the extent of the Galactic halo has been mapped to at least 100 kpc from the Sun and the Galactic center, showing the enormous extent of the spherical component of the Galaxy.

In addition, these RR Lyrae variables in the halo and in the thick disk are metal poor. The chemical elements heavier than He, Li, Be and B are between 5 and 150 times less abundant than in the Sun, providing important clues to events in the chemical evolution of the Galaxy. A small subset of RR-Lyrae-type variables in the disk do, however, have near-solar metallicity and population I low-velocity kinematics, providing additional clues, not yet deciphered, for Galactic evolution.

RR Lyraes as a distinct class of variable stars were discovered in 1893 when large numbers of them were found in globular clusters by Solon Bailey. Because of their high abundance in many globular clusters, they were initially called 'cluster-type variables' whether they occurred in clusters or the field.

The brightest of the class in the general field, discovered by W Fleming at Harvard in July 1899 by the technique of multiply exposed photographic plates, is the eponymous star RR Lyrae itself. Soon other similar variables in the field were discovered, and the identification was soon made between the characteristics of Fleming's short-period field variables and Bailey's cluster variables.

There are now more than 7000 RR Lyraes known in the field and 1990 in Galactic GLOBULAR CLUSTERS. The class accounts for 20% of the total of nearly 30 000 variables in the Russian standard *Fourth General Catalogue of Variable Stars* (1985 edition). However, the discovery is far from complete. A current estimate is that the Galaxy contains of the order of 100 000 RR Lyraes in the halo, with a still higher number in the thick disk and the galactic bulge.

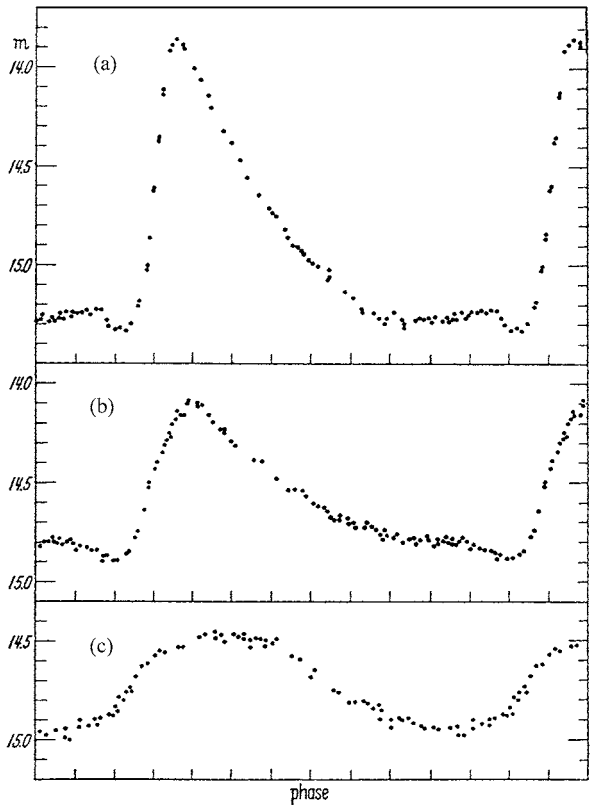

Figure 1. The light curve characteristics of the three Bailey types of RR Lyrae stars of classes a, b and c.

Shapes of the light curves

Bailey's early (1902) division into three classification groups, based on the shape of his light curves for the variables in the globular cluster omega Centauri, is still valid. We now know that this division into Bailey types, a, b and c is related to the physics of the internal forces that drive the self-sustaining pulsation according to the degree of energy dissipation that determines whether pulsation can occur.

Figure 1 shows typical light curves for the three Bailey RR Lyrae types. Type a variables (top panel) have a very steep rise to maximum light, usually taking only 10% of the period to go from minimum to maximum light. Moreover, the amplitude is largest in Bailey type a compared with the average amplitudes for types b and c. Type b variables have a more gradual rise to maximum, taking typically 20% of the period. The decline from maximum to minimum light is continuous rather than having the nearly flat light curve near minimum that is typical for Bailey type a variables.

The difference in the shapes of the light curves is undoubtedly due to a difference in the strength of the

Dirac House, Temple Back, Bristol, BS1 6BE, UK

mechanism that drives the pulsation. Struve in 1947, Sanford in 1949 and Preston and Paczynski in 1964 discovered that type *a* variables all show the hydrogen lines in emission for about 10 min midway on the rising light curve from minimum to maximum, whereas none of the type *b* and *c* variables shows the emission. The emission is interpreted to be caused by a shock wave in the rising gas in the highly non-linear and stronger pulsation push of the *a* type compared with *b* and *c* type variables. The non-linearity of the driving is seen directly by the highly asymmetrical light curves of Bailey types *a* and *b*.

Type *c* variables have more symmetrical light curves that are also of smaller amplitude than either type *a* or *b*. They also are bluer than *ab* variables (see next section), occupying the left portion (hotter temperature) of the instability strip of the HR diagram, and they have shorter periods. Type *c* variables are vibrating in the first overtone of the pulsation, whereas type *a* and *b* variables are vibrating in the fundamental mode.

In recent years a type called RRd has been introduced, based on the discovery of stars that are driven by a combination of both the fundamental and first overtone periods. These occur in a very narrow range in period at the transition between the type *c* and type *ab* variables. These stars are called double-mode cluster variables in the literature.

Finally, concerning light curve shapes, it is to be noted that a few, perhaps 15%, of the RRab stars show systematic shape variations that themselves are periodic. Said differently, a given shape appears again and again as in the beat modulation in the addition of two periodic functions with slightly different periods. In RR Lyrae itself, the return of the light curve to a given shape has a period of 41 days. The phenomenon is called the Blazhko effect. Blazhko periods, as known up to 1995, range from 11 days for AH Cam to 533 days for RS Boo. Smith (1995) states that 'though a number of hypotheses have been advanced, there is no accepted explanation for the Blazhko cycles'.

Importance for theories of stellar evolution, galactic structure and cosmology

The importance of RR Lyrae variables for a large number of astronomical problems stems from their unique place in the HR diagram on the horizontal branch of globular cluster color–magnitude diagrams, showing that they have only a small spread in absolute luminosity as a group. Shapley used this fact to derive the first reliable distances to globular clusters using the cluster-type variables to calibrate the brightest 25 stars near the tip of the giant branch of the HR diagram. The calibration of the absolute magnitude of RR Lyrae stars has occupied astronomers from 1915 to the present.

The variables have been central in such diverse studies as (1) the structure and age of the Galaxy, in both the disk and the halo components, (2) the age of globular clusters, (3) study of the advanced, post-main-sequence evolution state of the variables in the HR diagram, (4) study of the astrophysical processes of stellar pulsation as a problem in stellar structure that combines the physics of classical mechanics, hydrodynamics and thermodynamics, (5) an understanding of the position of the instability strip in the HR diagram and (6) the calibration of extragalactic distances and the expansion rate of the universe.

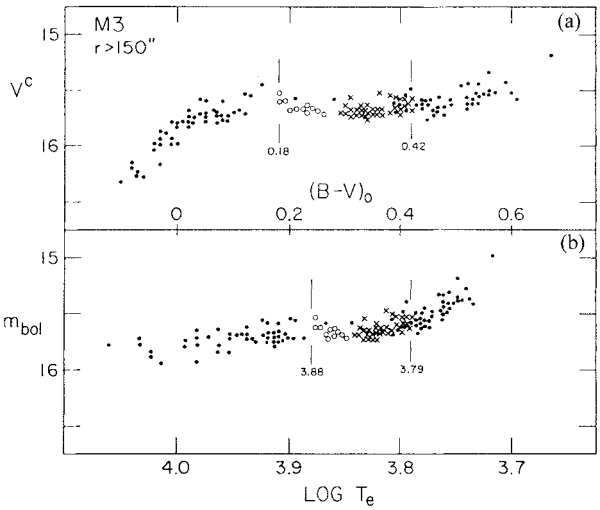

Figure 2. The observed position of the cluster variables in the globular cluster M3 along the horizontal branch. Circles in the instability strip are for Bailey type *c* variables. Crosses are for Bailey type *ab* variables. Type *c* variables are pulsating in the first overtone. Type *ab* variables pulsate in the fundamental mode.

Placing RR Lyrae variables in the HR diagram

In 1940 Martin Schwarzschild first showed that the RR Lyrae stars occur only within a small region the horizontal branch of the HR diagram of the globular cluster M3. The horizontal branch is populated by low-mass stars that have evolved from the main sequence to the tip of the giant branch, and after mass loss and the ignition of helium in the hydrogen-exhausted core have evolved from that tip at $M_V \sim -3$ to $M_V \sim +0.5$ mag The horizontal branch is a configuration of decreased radius and hotter surface temperature (see STELLAR EVOLUTION) and has only a small spread in absolute magnitude from cluster to cluster.

Schwarzschild's discovery of the cluster instability strip for the variables in M3 was soon extended as a general feature to all globular clusters whose horizontal branches covered the appropriate color range. His conclusion that 'stars which can pulsate do pulsate' was shown to be universal.

A modern mapping of the instability strip in the color–magnitude diagram of the globular cluster M3 is shown in figure 2. The top panel shows the photometric data for a complete sample of horizontal branch stars outside a radius of 2.5 arcmin from the cluster center, plotted at mean light.

The RR Lyrae domain occupies the color interval $0.18 < B{-}V < 0.42$. The Bailey type *c* variables (circles) are

separated in color (being bluer) from type *a* and *b* variables (crosses). The bottom panel shows the conversion of the data to bolometric apparent magnitudes and logarithm of the effective temperature. There is a sharp separation color (and temperature) between type *c* and type *a*, *b* variables in M3. However, in other clusters there is an overlap region occupied by both types.

The vertical boundary lines in figure 2 define the blue and red edges of the pulsator instability strip at the luminosity of the RR Lyrae stars. It is known that the strip continues vertically in the diagram, sloping slightly to cooler temperatures at luminosities that are fully 6 magnitudes brighter over the whole of the long-period Cepheid instability strip.

Properties of the instability strip

The parameters of (a) amplitude, (b) shape of light curve and (c) period vary systematically with color within the instability strip. In a given cluster the longest-period *ab* variables are at the red side of the strip; the shortest period are the bluest. This is the period–color relation. Clearly such a relation is demanded by the pulsation model where the period must vary with the inverse square root of the density, which can be expressed as a combination of mass and radius, and therefore of temperature at a given mass and luminosity. A period–color relation also exists for the variables in the cluster M15, which, however, is shifted by a factor of 1.2 in period at a given color relative to the relation in M3. The periods in M15 are longer.

The largest-amplitude light curves occur near the center of the strip, decreasing toward the red edge of the instability region. Because there is a period–color relation, this amplitude–color relation can be changed to an amplitude–period relation. The amplitude correlation is also shifted in M15 by again a factor of 1.2 in period relative to the relation in M3. The same is true of the light curve shapes, as measured by the rise times (in units of the period) from minimum light to maximum.

These correlations with their period shifts between M3 and M15 are shown in figure 3. The top panel shows the period–amplitude relation. The relation between period and the light curve shape, measured by the rise time, is in the bottom panel.

Because the metallicity is different for M3 and M15 (M3 is down by a factor of 50 in metals from the Sun; M15 is down by a factor of 150) the period shifts were suspected early on (in 1958) to be a metallicity effect. From studies of many clusters of different metallicities, the period shifts were found to be strongly correlated with metallicity. The effect is a generalization of the Oosterhoff–Arp–Preston period–metallicity correlation that provides an important method for the RR Lyrae absolute magnitude calibration (see next section). The period–metallicity correlation is obeyed both in the globular clusters and in the general field.

Figure 2 shows that, within a given cluster, the absolute *V* magnitudes of the RR Lyrae stars are closely the same. There is a small vertical dispersion in magnitude

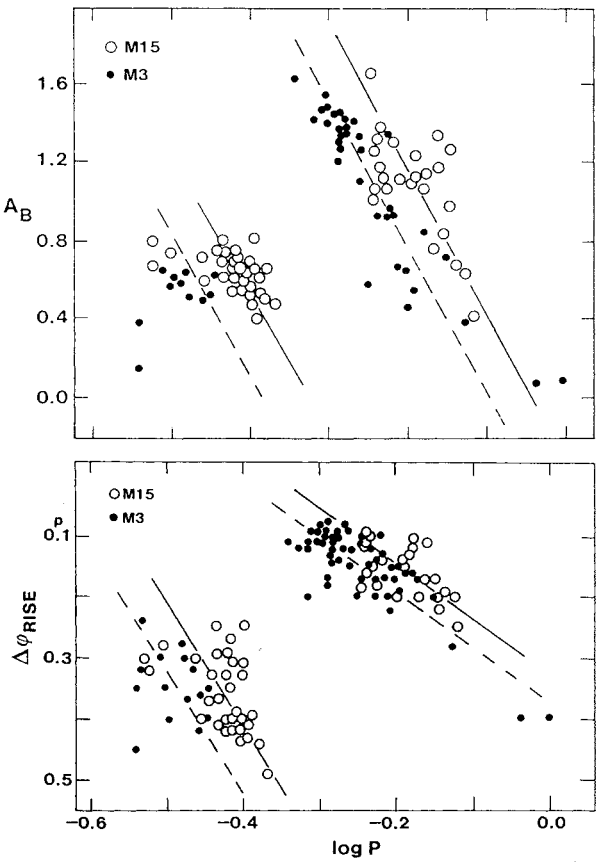

Figure 3. (top) The period shifts in the period–amplitude relation between the RR Lyrae stars in M3 and M15. The clusters have different metal abundances. (bottom) Same as the top but using the shape of the light curves as measured by the rise time (in phase units) from minimum to maximum light.

which has been shown to be real. It is caused by the evolution from the 'age zero' horizontal branch as the helium burning in the core proceeds. Proof that the dispersion in absolute magnitude is real, not due to observational error, is made by showing that the variables that are brighter have longer periods than the fainter cluster variables of the same color. This, of course, is required from the period–density relation. However, the dispersion is small, only at the 0.1 mag level. Most of the stars in a given cluster have a nearly constant *V* magnitude, showing that the RR Lyraes are excellent distance indicators once the metallicity dependence and the evolutionary effects can be calibrated out.

The expectation that there is a correlation of absolute magnitude with metallicity, required by the period shifts, is confirmed observationally. Figure 4 shows a composite color–magnitude diagram of seven globular clusters whose metallicities range from 2.5 times down from the Sun (NGC 6838) to 150 times smaller than the Sun (M15). All seven have horizontal branches, four of which thread the instability strip and have cluster variables, but at

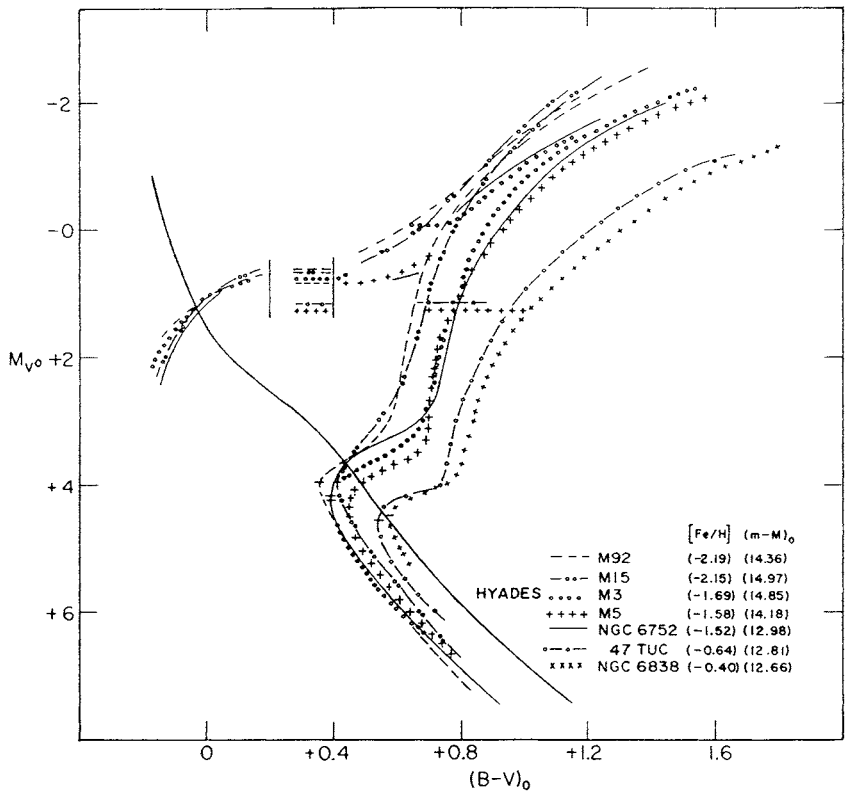

Figure 4. Composite HR diagram for seven globular clusters of different metallicity. Their absolute magnitude positions are set by main sequence fittings to the positions of fiducial main sequences as a function of metallicity. The sold curve from upper left to lower right is the position of the main sequence for stars of solar metallicity determined from trigonometric parallaxes.

different luminosities.

The cluster diagrams in figure 4 have been fitted vertically according to the expected fiducial main sequence positions as a function of metallicity (see HERTZSPRUNG–RUSSELL DIAGRAM and LARGE HOT SUBDWARFS AND EXTREME HORIZONTAL BRANCH STARS). From these main sequence normalizations, the spread in the vertical positions of the cluster variable instability strip as a function of metallicity is evident. This is the luminosity–metallicity relation that must be calibrated and accounted for in using RR Lyrae stars as distance indicators.

Calibration of the RR Lyrae absolute magnitudes

An early history

Shapley in 1918 was the first to calibrate the RR Lyrae absolute magnitudes. After calibration, he used his value of $\langle M_{\rm pg}({\rm RR})\rangle = -0.23$ to derive his famous new model of the Galaxy using his new distances to globular clusters which he had derived from the apparent brightness of the cluster variables in a few clusters. He then used these data as an intermediate step to calibrate the 25 brightest giant stars that could be more easily be measured in a large number of clusters. His radical new model of the Galaxy was that of a globular-cluster system that defined a distant center in the direction of Sagittarius, offset from the central position of the Sun that had been the main feature of the Galaxy model of Kapteyn.

His route to the RR Lyrae mean luminosity was to repeat Hertzsprung's 1913 luminosity calibration of the long-period field classical Cepheids. The method was that of statistical parallaxes to calibrate Leavitt's period–apparent luminosity curve for the long-period classical Cepheids in the Magellanic Clouds. Shapely then noted that a few globular clusters also had long-period variables which he took to be of the same type as the field Cepheids which he and Hertzsprung had just calibrated. Tying the cluster RR Lyrae to the cluster 'long-period Cepheids' and then tying this combination to the field Cepheids gave the RR Lyrae calibration quoted above as $\langle M_{\rm pg}\rangle = -0.23$.

Shapley's conclusion for a displaced center of the Galaxy and the consequent huge dimensions of the resulting Galaxy was so revolutionary that it was immediately challenged by Kapteyn and van Rhijn. These were the two greatest statistical astronomers of their day. They published what seemed to be a devastating, critical paper in 1922 in which they determined statistical parallaxes directly for the few field RR Lyraes whose proper motions were then known. Using the value of the solar motion relative to the slow-moving ordinary field stars, called now stars of population I, they derived a mean

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

absolute magnitude of $\langle M(\mathrm{RR})\rangle = +4.2$ which require a distance scale that was fully seven times smaller than Shapley's. Their scale would have returned the Galaxy back closer to Kapteyn's earlier small-scale model with the Sun near its center.

Shapley replied in a short note in *Harvard Bulletin 765* (1922), noting that his much brighter calibration was consistent with the discovery of RR-Lyrae-like variables in the SMC at $m_{\mathrm{pg}} = 16.1$. With the 'known' large distance of SMC from its classical Cepheids, which was not in contention by Kapteyn and van Rhijn, Shapley's claim that Magellanic Cloud RR Lyraes occur at $m_{\mathrm{pg}} = 16.1$ would clearly confirm his new RR Lyrae bright calibration near $M_{\mathrm{pg}} = 0$.

However, it is now known that Shapley's argument here is not correct. The true RR Lyrae stars that belong to SMC occur only at the much fainter level of $m_{\mathrm{pg}} = 19.6$. Either the variables noted but not identified by Shapley are foreground or, more likely, have longer periods than he believed. Nevertheless, Shapley's conclusion the $M(\mathrm{RR})$ is near $M(\mathrm{RR}) = 0$, not as faint as +4.4, was correct.

Shapley hints at the reason for the Kapteyn–van Rhijn incorrect conclusion by noting that the field RR Lyraes have a spherical spatial distribution, whereas the long-period Cepheids are confined to the plane, and therefore that the two types are different, requiring different precepts for the statistical parallax calculations. Nevertheless, his argument on this point is curious because Shapley himself, in his method through the cluster data calibrated with classical Cepheid field variables, had earlier combined the data for the two types as if they were related.

In a longer, much more closely reasoned reply, Shapley *(Harvard Circular* 237, 1922) points to the abnormally high radial velocity of RR Lyrae itself at -69 km s^{-1}, which is much higher than the radial velocity of any classical Cepheid. In addition, he pointed to the most unusual high proper motion of two of the Kapteyn–van Rhijn field variables, and therefore he correctly pointed out the high-velocity character of the spherically spread system of field RR Lyrae as a group. This requires that one must use a radically higher value for the solar motion for them than for the low-velocity population I objects for the statistical parallax calculation. The concept of the high-velocity stars and the nature of the Strömberg asymmetric drift was just coming into view in 1922, and Shapley again correctly identified the Strömberg drift of the RR Lyrae system, perhaps for the first time.

A number of direct determinations via statistical parallaxes, using a correctly high solar motion, were then made from 1922 to the present, all generally confirming Shapley's $\langle M(\mathrm{RR})\rangle \sim 0$ value. The two most important studies were by P F Bok and C D Boyd at Harvard in 1933 and R E Wilson at Mount Wilson in 1939 who had much more complete proper motion and radial velocity data than were available to Kapteyn and van Rhijn.

Because of the consistent results from the several new statistical parallax studies in the decades of the 1920s and 1930s, the problem was considered solved until Baade failed to resolve RR Lyraes in the disk of M31 with the Palomar 200 in telescope in the early 1950s. His result showed either that the classical Cepheid distance to M31 was incorrect (based on R E Wilson's 1939 recalibration of the classical Cepheid P–L relation) or that $\langle M(\mathrm{RR})\rangle$ had to be as faint as $\langle M(\mathrm{RR})\rangle \sim +2$. It was then that the method shown in figure 4 was introduced after the globular cluster main sequences had been identified beginning in the early 1950s showing, in fact, that $\langle M(\mathrm{RR})\rangle \sim 0$ was indeed correct.

Modern methods

Four principal modern methods have been used to determine the absolute magnitude of the RR Lyrae variables.

The three other methods besides that of statistical parallaxes are (1) the Baade–Becker–Wesselink way of combining the light and radial velocity curves to determine the radius of a pulsator, from which the absolute magnitude can be calculated from the radiation laws once the temperature is known (it must be measured independently), (2) pulsation theory together with the Oosterhoff–Arp–Preston metallicity effect to give the slope of the correlation of M_{bol} with [Fe/H], together with an independent method for the zero point, and (3) main sequence fitting of globular cluster color–magnitude diagrams to calibrate the absolute level of the horizontal branch as in figure 4.

The chief problem with the powerful main-sequence-fitting method is the lack of precise knowledge, at the 0.1 mag level, of the position of the fiducial main sequence as a function of metallicity. Eventually, precision trigonometric parallaxes from space interferometry measurements of a large sample of subdwarfs with a range of metallicity will solve this problem. Nevertheless, the method is now sufficiently accurate to show beyond doubt that the luminosities of the horizontal branches, and therefore of the cluster variables, is a function of metallicity (figure 4).

Present status of the calibration

The results of the four methods to derive $\langle M(\mathrm{RR})\rangle$ are in agreement at the 0.3 magnitude level, but there still remain (1999) systematic differences in $\langle M(\mathrm{RR})\rangle$ as a function of metallicity at that level.

Figure 5 compares the extant calibration using two of the four methods. The individual data points summarize results for individual field RR Lyraes determined by several independent groups using the Baade–Becker–Wesselink method. Details of the method that combines the light curve with the radial velocity curve to determine the stellar radius, and then the luminosity, are set out in a number of the references listed at the end, principal of which is the comprehensive review by Gautschy.

The line marked '*Oosterhoff pulsation*' in figure 5 uses the period ratios similar to those shown in figure 3 between RR Lyrae stars of different metallicities, but read

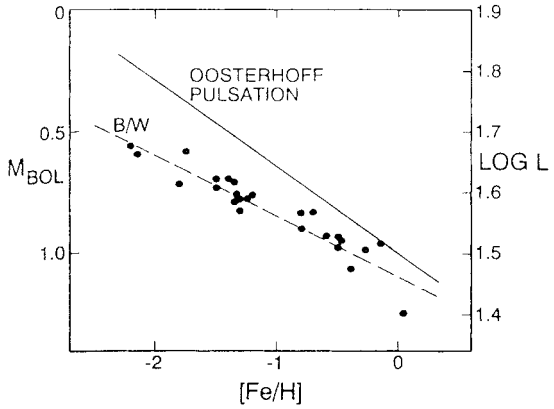

Figure 5. Comparison of the RR Lyrae star calibration (circa 1995) of the bolometric absolute magnitude determined using the Baade–Becker–Wesselink and the Oosterhoff–Arp–Preston metallicity-effect methods. The differences in the slope and zero points of the two correlations are crucial in the many applications of RR Lyrae stars to astronomical problems. The calibration of $\langle M(\mathrm{RR})\rangle$ as a function of metallicity is not yet (1999) solved at the level of the differences shown.

at the blue edge of the instability strip. The blue-edge periods are well correlated with metallicity at the rate of $\log P = -0.112[\mathrm{Fe/H}] - 0.500$, which, when put in the theoretical pulsation equation that relates the luminosity to the period, temperature and mass, predicts the pulsation relation in figure 5. Conversion to M_V gives the calibration as $M_V(\mathrm{RR}) = 0.30[\mathrm{Fe/H}] + 0.94$. A detailed account of the method can be found in the first paper in the *IAU Symposium 139* conference report cited in the bibliography.

Astronomical used of RR Lyraes in clusters and in the field

Because RR Lyrae variables are such excellent standard candles once the metallicity dependence is calibrated out, and because they are relatively bright at $\langle M\rangle \sim 0.5$, they have been used for many purposes. Among many we list five. An extensive literature exists for each.

(1) The system of field RR Lyrae stars shows the Strömberg asymmetric drift in its kinematics. This, of course must be accounted for in the calculations for statistical parallax, but simply its existence as a function of metallicity gives an important clue to the chemical and dynamic evolution of the Galaxy. The asymmetric drift velocity varies from $\langle V\rangle \sim -50$ km s^{-1} for RR Lyraes with solar metallicity to $\langle V\rangle \sim -250$ km s^{-1} for the most metal-poor variables of the extreme population II. Many of the latter are on retrograde galactic orbits. The early history of the collapse of the protogalaxy as a function of time and of the progressive chemical enrichment of the disk and halo can be studied from such data.

(2) Because of the large amplitudes of their light curves and their short periods, RR Lyraes are easy to discover. They have been extensively used in studies of Galactic structure. Among other data, they provide the identification of stellar populations in the halo, bulge, center and the thick disk components of the Galaxy. Two large surveys for RR Lyraes in the halo, one by Saha at Palomar and the other by Kinman at Lick, have mapped the extent of the halo and have determined the density distribution in various directions at high Galactic latitude. A large discovery survey in the bulge has been completed at Palomar by Plaut to determine the population characteristics at intermediate latitudes in the bulge toward the Galactic center.

(3) The ages of globular clusters have been determined to be 13 billion years by comparing the difference in apparent magnitude of the RR Lyraes and the main sequence turn-off point in globular clusters of different metallicities. The question of whether there is an age–metallicity relation for the clusters depends on which RR Lyrae absolute magnitude calibration as a function of metallicity is used. If the steep metallicity dependence is used that is required to explain the Oosterhoff–Arp–Preston effect (see previous section), then all globular clusters are closely the same age. However, if the more shallow dependence of $M_V(\mathrm{RR})$ on metallicity (figure 5) is used that is determined by Baade–Becker–Wesselink methods, then there would be an age–metallicity variation for the globular clusters. The sense would then be that metal–poor clusters would be older than the more metal-rich clusters by several billion years. The problem has not been resolved at the time of writing (1999).

(4) One way to test whether the period–luminosity relation for the long-period classical Cepheids depends on metallicity is to compare the distance to a given galaxy determined by its RR Lyrae stars and independently by its classical Cepheids using a CEPHID PERIOD–LUMINOSITY RELATION with no metallicity term. If the two distances agree, then no metallicity correction would be need for the long-period Cepheids. Of course, a correct RR Lyrae–metallicity calibration is required to make the test. At the time of writing, with the several versions of the RR Lyrae calibration extant as in figure 5, the method, although very powerful in principle, is not yet definitive. The metallicity dependence of the RR Lyrae calibration is the centerpiece here.

(5) The physics of the pulsational instability of stars and of the mechanism that drives the pulsation has been understood at a deep level by comparing the theoretical pulsation calculations with various observed aspects of light and velocity variations of both the RR Lyrae stars and the long-period classical Cepheids. The literature is vast. The theory is elegant. The agreement between theory and observations is excellent. The subject is one of the major triumphs of modern astrophysics (see STELLAR PULSATION).

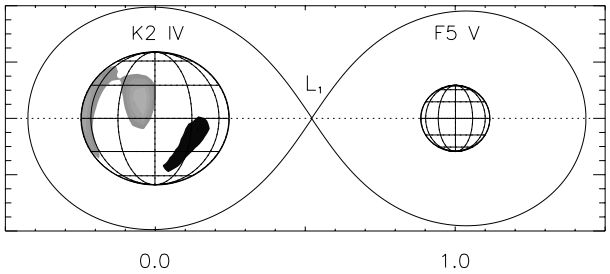

Figure 1. A three-dimensional map of the close binary system RS CVn, the prototype of a class of intrinsically variable systems showing solar-like activity phenomena of magnetic origin, as derived from cool spot modelling of the 1964 optical light curve (Rodonò *et al* 1995). The projected two-dimensional Roche lobes in the plane of sky and the inner Lagrangian point (L_1) are also shown.

RS Canum Venaticorum

RS CVn = RS Canum Venaticorum (BD +36° 2344, HD 114519; $\alpha_{1950.0} = 13^h08^m18^s$, $\delta 1950.0 = +36°12'.0$; $\Delta d = 2.79$ s yr^{-1}, $\Delta\delta = -0.319'$ yr^{-1}) is a detached CLOSE BINARY STAR (F5 V+K2 IV) in the CANES VENATICI constellation (cf Rodonò *et al* 1995 for a discussion of the spectral classification). In addition to the canonical eclipse-related light variability, early photometric observations had already shown uneven outside-of-eclipse maxima suggesting low-amplitude intrinsic variability of the component stars, which led to the classification of RS CVn as an intrinsically VARIABLE STAR in the *General Catalogue of Variable Stars*. An illustrative map of the RS CVn system is shown in figure 1.

RS CVn is considered the prototype of a class of close binaries with outside-of-eclipse variability in optical light essentially consisting of a so-called 'wave-like distortion' or 'photometric wave' (figure 2), which is characterized by an amplitude up to a few tenths of a magnitude, variable on time scales from several months to years. Moreover, this 'photometric wave' usually systematically moves towards decreasing orbital phases at a variable rate. This peculiar optical behavior can be ascribed to one or both components of the binary system by assuming that their rotation periods are slightly shorter than the orbital period, so that the dark or bright surface inhomogeneities producing the observed variability appear on the visible stellar hemisphere(s) at systematically decreasing orbital phases. Actually, the first interpretation of this phenomenon, as suggested by Rodonò (1965) soon after he discovered the systematic variability of the RS CVn light curve, was that solar-like activity phenomena, such as dark spots or bright PLAGES, form in the photosphere of one or both components, so that the visibility of such surface features, and the related effects on the optical light curve, are modulated by the star's rotation. A slightly asynchronous rotation of the spot-forming region on a differentially rotating photosphere may account for the characteristic variability and its systematic backwards drift on the light curve. Most of the RS CVn systems show a 'photometric wave' that migrates towards decreasing orbital phases, but in a few cases where the reverse situation is observed and in a few other systems (SS Boo, V 711 Tau, CG Cyg, AR Lac) changes of the migration direction have occurred (see also STELLAR PHOTOMETRY). Moreover, for SS Boo and V 711 Tau there is some evidence of cyclic changes in the migration direction. Stellar spots and flares, which are occasionally observed as well (cf Catalano 1990), appear to be orders of magnitude more powerful and extended than on the Sun.

The identification of a new class of variable stars, named after the prototype system RS CVn, was proposed by Oliver (1974) and Hall (1976), who, in addition to the already mentioned photometric wave and the well-known presence of Ca II H and K emission lines in their spectra, identified the following distinctive characteristics of RS CVn close binaries: (a) 'undersized' subgiant component, well within its ROCHE LOBE, (b) fast rotation, i.e. almost synchronized binaries with orbital periods shorter than about 15 days and (c) orbital period variation (for further details see the review articles by Rodonò 1983, Catalano 1983, Hall 1991, Rodonò 1992).

In addition to spots and flares, RS CVn stars show a rather complete set of solar-like activity signatures, such as chromospheric and transition region bright plages, as derived from synoptic studies of enhanced UV line (Rodonò *et al* 1986, 1987, Neff *et al* 1989, Linsky *et al* 1989), coronal x-ray (Walter *et al* 1983, White *et al* 1990, Rodonò *et al* 1999) and microwave (Gibson and Hijellming 1985, Trigilio *et al* 1993, Umana *et al* 1995) emissions. In non-optical wavelength domains, the quiescent flux from late-type cool stars being rather low, the characteristic high-temperature flare phenomena are best observed for contrast effects. In a rather complete compilation of magnetic activity signatures detected on stars (Linsky 1988), only two question marks concerning the detection of magnetic fields and optical flares were listed. Both question marks were positively answered within a few years (Saar 1988; Donati *et al* 1990; Foing *et al* 1991).

Activity phenomena of presumably magnetic origin have been detected also on other types of close binaries, e.g. BY Dra type (Bopp and Fekel 1977, Rodonò 1983) and UV Cet type M–K dwarfs (Rodonò 1990), W UMa type contact systems (Eaton *et al* 1980), Algols (Olson 1984) and cataclysmic variables (Bianchini 1990). These different types of binary systems share the common properties that one or both component stars have deep convection zones. Since they are tidally locked close binaries, they are also fast rotators. These same two factors (deep convection and rapid rotation) also exist in several types of single stars that display the very same activity phenomena (Hall 1991). When these two conditions are met, an α–ω dynamo can efficiently operate at the base of the convection zone (see DYNAMOS: SOLAR AND STELLAR). This leads, with a sometime substantial contribution of surface turbulence, to strong intensification of the star's magnetic fields. When the magnetic pressure surpasses the gas pressure, magnetic flux tubes can emerge at the stellar surface giving rise to the

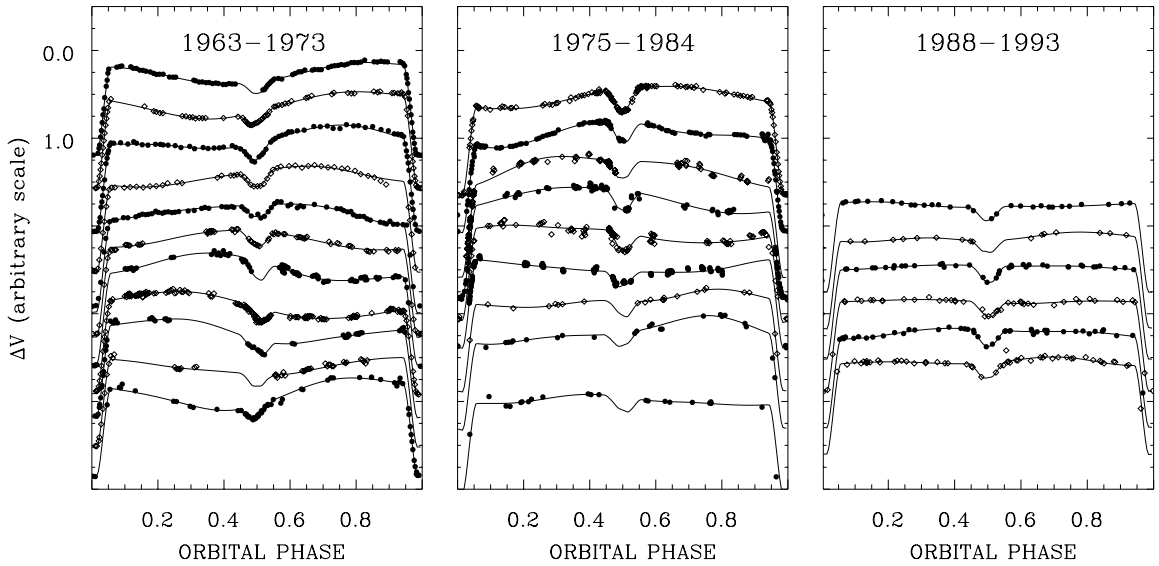

Figure 2. A sequence of RS CVn light curves over a 30 yr interval showing the characteristic 'wave-like distortion' or 'photometric wave' that migrates toward decreasing orbital phases. Each yearly light curve is shifted vertically with respect to the previous one. A blank vertical space is left if observations are not available. The thin continuous curves are maximum-entropy spot-model fits by Rodonò *et al* (1995). Most of the plotted data were obtained at Catania Astrophysical Observatory, where systematic photometry of RS CVn systems and other magnetically active stars has been carried out since 1963 (Rodonò 1965, Chisari and Lacona 1965).

whole panoply of activity phenomena that are observed on the Sun and several other late-type stars. The emerging magnetic loops interact with pre-existing ones and the subsequent magnetic line reconnections lead to energy dissipation. Therefore, magnetic fields appear to be the principal energy source of the observed phenomena.

Among magnetically active stars, RS CVn binaries offer, however, the cleanest, rather stable and understandable phenomena, when compared, for example, with the complex variability of contact binaries or binaries containing a degenerate component, where other types of phenomena simultaneously contribute to the observed variability. This makes it rather difficult to identify and disentangle pure solar-like activity phenomena from the observations and, consequently, it renders rather uncertain their study and interpretation.

In addition to allowing us to study the physical characteristics of surface activity phenomena, the monitoring of RS CVn stars and other active systems has led to the detection of activity cycles (see Strassmeier *et al* 1993) and has triggered the study of their effects on the star and system dynamics (see also STELLAR DYNAMICS): short-term variations of the orbital period appear to be compatible with changes of the quadrupole moment of the active component that are produced by the modulation of the star's internal magnetic field and angular momentum distribution throughout a magnetic cycle (Lanza and Rodonò 1999).

In conclusion, RS CVn systems offer one of the best and most complete astrophysical laboratories for studying solar-like activity phenomena in stellar photospheres and overlying atmospheric layers up to corona levels.

Runaway Star

Term used to describe a star that is moving with very high velocity, typically hundreds of kilometers per second, relative to the local standard of rest. Such exceptionally high velocity presumably indicates an 'explosive' departure of the star from the location of its formation. The most likely explanation of this is that the star was a minor component of a binary system, ejected when the primary component exploded as a supernova.

Russell, Henry Norris (1877–1957)

Astronomer, born in Oyster Bay, NY, spent nearly all his life working at Princeton University. He spectroscopically studied eclipsing binary stars to determine the masses of their component stars. At first collaborating with the British astronomer Hinks at Cambridge, he started to measure stellar parallaxes and, plotting the absolute magnitudes of stars whose distance he had thus measured, against their spectral types, he found the correlation now known as the main sequence of the *Hertzsprung–Russell diagram*. He distinguished between giant stars and dwarfs. He proposed that stars cooled along this correlation. This theory of stellar evolution was superseded, but the H–R diagram continues to provide a tool with which to test theories of stellar evolution. Russell applied MEGHNAD SAHA'S theory of ionization to stellar atmospheres and determined the abundance of the elements in stars, including, after the foundation work by CECILIA PAYNE-GAPOSCHKIN, the great abundance of hydrogen. In the theory of stellar structure, he showed that the size, temperature, etc, of a star at each stage of its evolution can be found solely from its mass, chemical composition and age (the *Vogt–Russell theorem*).

Russian Astronomy

Russia is a vast multinational country whose boundaries have been changed to a great extent. The Russian Empire at the beginning of this century included many countries, which are now independent states. This article is concentrated on the history of astronomy and current activity on the territory of modern Russia with necessary brief astronomical excursions in the history of the states.

History

Archaeo-astronomical studies in Russia have brought some material evidence of astronomical knowledge of previous generations (e.g. thousand year old ring and rod inscribed with a primitive astronomical calendar found in an excavation near Achinsk in Siberia). The first astronomical observatory was established in 1690 by the archbishop of Archangel'sk for navigational purposes. In 1701 the Russian tsar Peter the Great who was highly impressed by his visit to Greenwich and Copenhagen observatories established in Moscow 'The School for Navigation and Mathematics' with an astronomical observatory, which was headed by J Bruce. In 1725 the Astronomical Observatory of the Petersburg Academy of Sciences was founded. The well-known French astronomer Joseph-Nicolas DELISLE was the first director of this well-equipped (according to the standards of that epoch) observatory.

In the 18th century most astronomical observations, both at observatories and during numerous expeditions, were aimed to maintain a network of points with accurate coordinates. Thus the 'Catalogue of astronomical coordinates' by S Rumovsky contained coordinates of 82 points with an accuracy, good for that period, of 8′. The first astrophysically important observation was carried out by a famous Russian scientist of encyclopedic knowledge, M LOMONOSOV, who in 1762 observed the passage of Venus across the solar disk and discovered the atmosphere of that planet. Growing industrial and military needs caused quick development of astrometry and practical astronomy in Russia, which led to the construction of new observational facilities.

In the 19th century new observatories at Kharkov (1808), Derpt (Tartu) (1809), Nikolaev (1827), Kiev (1845) and Odessa (1871) universities were built. In 1831 the construction of a new Moscow observatory began. However, the most prominent event in Russian astronomy of the 19th century was the construction of the Pulkovo Observatory (figure 1). This observatory was founded in 1839. The first director of the observatory was the famous astronomer Vassily (Wilhelm) STRUVE, well known for his classical studies of double stars and for his guess (1847) about the existence of interstellar absorption. Because of the outstanding organizational abilities of its first director, the Pulkovo Observatory in 30 yr after its foundation became one of the world's best astronomical institutions and had unprecedented high-precision astrometric instruments. Pulkovo fundamental stellar catalogues of 1845, 1865, 1885, 1905, 1930 and 1955 were most precise and the observations performed in Pulkovo were included into the world's popular fundamental catalogues with the highest weight. Stellar astronomy also was a field of interest to astronomers from Pulkovo. The world's best instruments were installed at Pulkovo observatory, e.g. a REFRACTOR with $D = 76$ cm (1885). This telescope was destroyed (as were almost all the instruments and buildings of the observatory) by fascist troops attacking Leningrad during World War II. In the second half of the 19th century astrophysics in Russia was developing too. The theory of cometary tails (F Bredikhin, 1862–1877) and the first observational evidence of periodic changes of the radial velocity in δ Cep (which turned out to be typical for cepheids) were the most important contributions of Russian astrophysicists of the 19th century.

The very beginning of the 20th century was relatively favorable for the development of astronomy in Russia. New observatories at the Kazan University (1901), L'vov University (1907) and Simeiz Observatory (1908) were built. World War I and the October revolution, followed by years of economic dislocation, were negative factors for science in Russia. In 1922–1924 an important discovery was made by A FRIEDMANN, who found non-stationary solutions of the Einstein equations and thus contributed to the fundamentals of cosmology.

In the period of the strengthening of the state in 1930s new observatories were built (in ABASTUMANI—1932 and Irkutsk—1931) and new big plans of scientific development were elaborated. The leading role of the Academy of Sciences in fundamental research was then consolidated. An all-Union coordination body—the Astronomical Council of the USSR Academy of Sciences—was established in 1936. Members of this body were responsible for strategic planning of astronomical research in the USSR. New approaches were advanced. World War II prevented the realization of these ambitious plans.

After the war intensive investments in fundamental science (particularly in astronomy) brought a flourishing period. Astrophysical instruments require particularly dark and clean skies, so the best places for the new observatories were found in the southern mountains. Construction of the new large CRIMEAN ASTROPHYSICAL OBSERVATORY (CrAO) (1945–1954), BYURAKAN ASTROPHYSICAL OBSERVATORY (1946–1956), observatories near Alma-Ata (1951), Ashkhabad (1946), Goloseevo (founded in 1944), Dushanbe (1958), Shemakha (1960) and a solar station near Kislovodsk were essential steps of postwar development. The Pulkovo Observatory was reconstructed. Great progress in radioastronomy was not missed in the USSR (as happened with cybernetics and genetics) and new instruments and dedicated observatories were built. The radioastronomical station of the Institute of Radio Physics near Gorky (1949), radioastronomical station of the Lebedev Physical Institute (1956), radioastronomical observatory in Latvia (1958), radio telescopes in CrAO, Kharkov etc were evidence of attention to radioastronomy.

Figure 1. Pulkovo Observatory reconstructed after World War II.

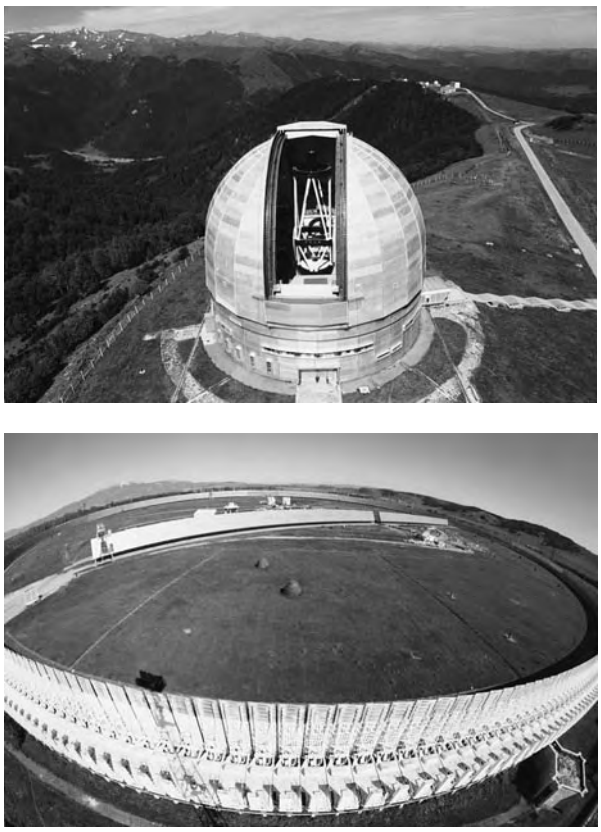

Figure 2. Special Astrophysical Observatory in the Caucasus: top—Large Alt-azimuth Telescope, bottom—RATAN-600 radio telescope.

Prominent discoveries of that period were made by V AMBARTSUMIAN (young stellar associations—1947, ideas on the important role of nuclei in active galaxies—1958) and I SHKLOVSKII (ideas on the observation of interstellar molecules in the radio range—1949, on the formation of planetary nebulae by red giants loosing their mass at the latest stages of stellar evolution—1956).

The peak of this postwar thriving of ground-based astronomy was marked by the construction of the SPECIAL ASTROPHYSICAL OBSERVATORY (SAO) in North Caucasus (1966–1976) (figure 2). This was a nationwide project which required huge resources. The 6 m optical telescope was for a long time the world's largest one. The unique 600 m radio telescope RATAN-600 even now is one of the most powerful instruments in the world. The 6 m telescope is located in a region whose astroclimate is far from ideal (although this place seems to be one of the best in the Russian Federation); that is why new astronomical centers were built in the Pamir region where places with record seeing parameters were found. All-Union observatories in Mydanak and Sanglok were the most promising for development of observational facilities in the USSR. At the same time space astronomy was quickly developing.

The serious problem was the lack of modern detectors (and computers) as a consequence of the general lag of the USSR in some high-technology fields. That substantially reduced the efficiency of large optical astronomical instrumentation. Thanks to international cooperation this situation was somewhat improved. A special program for the design and implementation of modern astronomical detectors was supported by the Academy of Sciences but the epoch was over.

During and after the 'perestroika' period the economic situation in the USSR drastically worsened. This immediately influenced scientific development. In the last 15 yr no new observatories and no large instruments have been built. All programs including prestigious space experiments were slowed down or stopped. After the disintegration of the USSR, Russia and other former USSR (fSU) republics were busy with political and social problems. Strong economic and sometimes political boundaries appeared. Most observatories are located outside Russia and this prevents effective use of them. Regular funds for astronomy as well as for other fundamental sciences in Russia were cut at least by an order of magnitude. In the process of intensive social separation the Russian astronomers (as most of population) quickly sank close to the social bottom. The various support programs were initiated by the world astronomical community to help Russian astronomers. Yet Russia remains a major astronomical country.

Astronomical institutions

Astronomy in Russia is a matter of research in academic institutions (those of the Russian Academy of Sciences—RAS) and at some universities.

The SAO (of the RAS) is Russia's main center for ground-based space research. The observatory is located in the south of Russia, in the Caucasus mountains of Karachaevo-Cherkessia. The main instruments of the observatory are the optical telescope BTA (Large Alt-azimuth Telescope) which primary mirror has a diameter of 6 m and the radio telescope RATAN-600 with an antenna diameter of 600 m. The observatory has highly experienced experts and modern detectors (some of them were provided by international cooperation). Study

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

of the universe as a whole, analysis of non-stationary energetic processes in galactic and extragalactic objects of various types, investigation of evolution and chemical composition of our Galaxy and the nature of solar activity and the ecology of the upper atmosphere and nearby space are basic research activities of the observatory.

The Main Astronomical Observatory of the RAS (Pulkovo Observatory) is located in the suburb of a big city. The observatory lost its own observational facilities in the south and researchers actively seek (and develop) cooperation with observatories over the world. Stellar astronomy, astrophysics and solar research remain as prime research directions of the observatory.

The Institute of Applied Astronomy of the RAS in St Petersburg has newly built observational facilities—30 m dish radio telescopes over Russia, originally designed for the construction of national time-coordinate system.

The Institute of Astronomy of the RAS (former Astronomical Council) is situated in Moscow. Research directions of the institute include astrophysics and astronomical data processing. Zvenigorod Observatory of the institute was specialized for tracking satellites and relevant basic research (Earth rotation, geodynamics, study of near-Earth objects).

The Astro Space Center of the Lebedev Physical Institute of the RAS, whose own main observational facility is a 22 m radio telescope in Pushchino, is carrying out studies of cosmology, physics of extragalactic objects and interstellar matter.

The Radio-Astronomical Station of the Institute of Radio Physics in Gorky is involved in studies of interstellar matter.

Sternberg State Astronomical Institute of Moscow University is a large institution with multidirectional research activity: cosmology, astrophysics, celestial mechanics, astrometry etc.

There are also smaller university observatories and institutes in St Petersburg, Kazan, Ekaterinburg and research groups in some other high schools. Big groups of experts in high-energy astrophysics and planetary research work in the Space Research Institute of the RAS (Moscow). Groups for solar physics and solar–terrestrial relations work in the Institute of Terrestrial Magnetism and Propagation of Radio Waves of the RAS in Troitsk (and a similar institution in Irkutsk) and small groups for theoretical astrophysics do studies in other research centers.

Space astronomy

In the USSR the number of astronomical experiments in space was continuously increasing. Numerous experiments on board Mir and Salyut stations in the field of high-energy astrophysics and solar physics as well as many dedicated missions to the Moon, Venus, Mars, Halley's comet, missions for study of solar–terrestrial relations and the Sun and the astrophysical missions ASTRON (80 cm telescope for UV spectroscopy), GRANAT (high-energy astrophysics) and RELICT (microwave background measurement) were carried out successfully. In the last 10 yr Russia has reduced ambitions in the field but still has a rather big space program. The RAS is responsible for preparation of the program of fundamental research. The RUSSIAN AVIATION AND SPACE AGENCY provides the general control and funding, while the scientific institutions are the main contractors for the following projects: SPECTRUM-X-GAMMA—a high-energy observatory (Space Research Institute), Spectrum-R—a radio interferometer with a space 10 m aperture radio telescope and base distance 70 000 km (Astro Space Center), Spectrum-UV—a general-purpose observatory with a 170 cm aperture UV–optical telescope equipped with spectrographs, imaging camera and polarimeter (Institute of Astronomy), CORONAS-F—project for investigating solar–terrestrial relations (Institute of Terrestrial Magnetism and Propagation of Radio Waves), 'Fobos-Ground'—delivery of a sample of the Fobos soil to the Earth (Space Research Institute). In the last few years the space program has encountered serious financial difficulties and launch dates are somewhat indefinite, which worries the Russian project teams as well as international cooperations.

Organizational features

Researchers. The total number of professional astronomers as estimated at the beginning of 1999 is about 1000 (members of the IAU—300, members of the EAS—250).

Funding. Most astronomical institutions are funded by the state via RAS or the Ministry of Education. Annual expenditures for astronomy (except space projects) in 1999 are expected to be equivalent to US$3.5 million.

Coordinating bodies. General cooperation in fundamental research is carried out by the scientific councils (SCs). In 1999 the list of the councils included the SC for astronomy, SC for physics of the solar system, SC for solar–terrestrial relations and the Space Council (includes sections for space astronomy, solar system, cosmic rays etc). All four are established by the RAS. The Council for Education in Astronomy was established by the Ministry of Education. The councils include leading persons in the field and are devoted to strategic planning of research and educational policy in astronomy.

Astronomical societies in Russia. These began to appear from 1890 (Russian Astronomical Society, Petersburg). The most long-lived society was the semiprofessional All-Union Astronomical-Geodetic Society (founded in 1932). The first fully professional society (The EURO-ASIAN ASTRONOMICAL SOCIETY—EAAS) was established in 1990. It is officially legalized as an international society. The EAAS performs its activities mainly on the territory of the fSU. The main goals of the EAAS are to maintain the development of astronomy and to reinforce scientific contacts between astronomers of the fSU and their colleagues all over the world. About 700 professional astronomers from Russia and the other fSU countries are members of the society. The EAAS has been affiliated to the EAS since 1992.

Astronomical journals. The main professional journal published in Russia is *Astronomicheski Zhurnal* (*Astronomy Reports*); two others are *Pis'ma in Astronomicheski Zhurnal* (*Astronomy Letters*) and *Astronomicheski Vestnik* (*Solar System Research*). Some institutions have non-regular series of publications.

Russian Aviation and Space Agency

The Russian Space Agency (RKA) was created on 25 February 1992 by a decree issued by the President of the Russian Federation. It was formed after the break-up of the former Soviet Union and the dissolution of the Soviet space program. The RKA uses the technology and launch sites that belonged to the former Soviet space program. This includes payment to Kazakhstan for use of the Baikonur Cosmodrome.

The official responsibilities of the RKA were codified in August 1993, in the Russian Federation Law on Space. It defines the state policy in space research and exploration for peaceful purposes, and execution of the Federal space program. This includes promotion of Russia's interests in the international space arena.

RKA has centralized control of Russia's civilian space program, including all manned and unmanned non-military space flights. The agency now oversees a growing number of bilateral and multilateral accords with other national space agencies, e.g. the Shuttle–Mir program and the International Space Station.

Since 1994, the agency has gained greater power over Russian industrial concerns. Under the 1994 government decree, 38 enterprises of the rocket and space industry were transferred to RKA. In 1998 RKA was given a control over 38 more state companies and federal shares in 22 joint-stock companies. On 11 March 1999 it was announced that RKA would gain control over 350 companies of the aviation industry and be renamed the 'Russian Aviation and Space Agency'.

Rutherford Appleton Laboratory

One of three sites operated since 1995 by the UK Central Laboratory of the Research Councils. Located in Chilton, Oxfordshire.

In association with university science groups, the Rutherford Appleton Laboratory (RAL) space science department is involved in the design, construction, test and management of space instrumentation as well as reception, processing and distribution of space data.

RAL has a significant role in many space missions, including the Infrared Space Observatory (ISO); the ERS, Envisat and Meteosat Earth observation projects; the ROSAT and Spectrum-X high-energy astronomy missions; SOHO and Cluster which study the Sun–Earth connection; the Rosetta comet mission; and the Earth Observing System.

Specialist facilities include class-100 clean rooms, a full range of environmental test facilities, optical design and test facilities, a satellite control center, geophysical and solar–terrestrial data facilities and a molecular spectroscopy facility.

In addition to the space activities, RAL is actively involved in research into particle physics, high-power lasers, computing, cryogenics and microelectronics.

RAL's principal customers are the UK research councils, the British National Space Centre, the UK Meteorological Office, ESA, NASA, institutes of higher education and industry.

The astrophysics division undertakes research and projects in space science. Research covers astronomy and solar system science in the areas of space plasma physics, solar physics and planetary science. Project work involves space instruments in these areas and the provision of science support to programs undertaken in other divisions.

Ryle, Sir Martin (1918–84)

British radioastronomer, Nobel prizewinner (1974) for pioneering research in radio astrophysics, in particular for his invention of the aperture synthesis technique. During the Second World War worked on the development of radar and joined the Cavendish Laboratory, Cambridge, becoming professor there. In 1972 he was appointed Astronomer Royal, the first such appointment as an honorary post unconnected with the Royal Observatory. He invented radio interferometry and determined accurate positions and fluxes for radio sources. This led to the identification of many sources with galaxies that could be studied in visible light, revealing their nature. He compiled catalogs of radio sources that provided a body of statistical information about the numbers of sources at fainter and fainter fluxes (and therefore greater and greater distances) which proved that the universe had evolved, i.e. started from a Big Bang. This was the first of several near-fatal blows to the credibility of the steady state model, championed by his disputative Cambridge colleague FRED HOYLE, before the theory was finished off by the discovery of the microwave background radiation. Ryle invented aperture synthesis, by which an interferometer, rotating on the Earth, could fill in the aperture of a virtual large radio telescope. This created the method by which radioastronomers can produce unsurpassed angular resolution, studying phenomena close to the central black holes in radio galaxies, for example.

Sabine, Sir Edward (1788–1883)

Physicist, astronomer, soldier and explorer, born in Dublin. He was the astronomer on two expeditions to the Arctic regions. He carried out experiments with pendulum clocks to measure the force of gravity at Spitzbergen and in Africa, in order to determine the shape of the Earth and studied terrestrial magnetism. Inspired by the work of HEINRICH SCHWABE on the 11 year cycle of sunspots, as reported by ALEXANDER VON HUMBOLDT, he correlated hiss measurements and his compilations of magnetic data and found a similar periodicity in magnetic storms, evidence of a solar influence on the magnetic field of the Earth.

Sadler, Donald H (1908–87)

Mathematician, became superintendent of the Nautical Almanac Office at the Royal Greenwich Observatory. His expertise was in numerical analysis, tabulation and printing, and he applied these skills to the production of the *Nautical Almanac*, and took pride in the accuracy of computation and reproduction.

Sagan, Carl Edward (1934–96)

Planetary scientist, born in Brooklyn, NY, became professor at Cornell University and director of its Laboratory for Planetary Studies. He directed programs on theoretical, laboratory and spacecraft studies of organic molecules in the atmospheres and on the surfaces of planets, satellites and comets in the solar system, and in the interstellar medium. This was a means of understanding the origin of life on Earth and the possibility of the present or past existence of life elsewhere in the solar system. He was very influential in NASA, playing key roles in the Apollo program to the Moon, and the Mariner, Viking, Voyager and Galileo expeditions to the planets. He helped identify the runaway greenhouse effect on Venus which produces its high temperature, the dust storms which cause seasonal changes on Mars, and the complex organic molecules which cause the reddish haze of Titan and are the building blocks of proteins and nucleic acids. He inspired the continuing search for extraterrestrial intelligence, and his novel on the subject, *Contact*, was made into a successful film. He was a very successful popularizer of astronomy, with a book and TV series called *Cosmos*.

Sagitta

(the Arrow; abbrev. Sge, gen. Sagittae; area 80 sq. deg.) A northern constellation which lies between Vulpecula and Aquila, and culminates at midnight in mid-July. Its origin dates back at least to ancient Greece, where it was identified (by different authorities) with arrows belonging to Eros, Apollo and Hercules in Greek mythology. The brightest stars of Sagitta were cataloged by Ptolemy (*c.* AD 100–175) in the *Almagest*.

A small but distinctive constellation, the brightest stars in Sagitta are γ Saggitae, magnitude 3.5, and δ Sagittae, magnitude 3.7. There are no other stars brighter than fourth magnitude. ζ Sagittae is a triple system with bluish-white (A1) and bluish components, magnitudes 5.6 and 9.0, separation 8.3″, the former of which has a very close (separation 0.2″) bluish-white (A3) companion, magnitude 6.0, which revolves around it in 22.8 years. Interesting variable stars include U Sagittae (range 6.45–9.3, period 3.38 days), an eclipsing binary, and WZ Sagittae (range 7.0–15.5), a recurrent nova which is normally about fourteenth magnitude but flared up to seventh to eighth magnitude in 1913, 1946 and 1978.

The Milky Way passes through Sagitta and the constellation contains a number of star clusters and planetary nebulae, the brightest of which is M71 (NGC 6838), an eighth-magnitude globular cluster.

Sagittarius

(the Archer; abbrev. Sgr, gen. Sagittarii; area 867 sq. deg.) A southern zodiacal constellation which lies between Ophiuchus and Capricornus, and culminates at midnight in early July. Its origin dates back to Sumerian times, when it was identified with Nergal, a god of war, but today it is associated with Crotus, son of the Greek god Pan and the inventor of archery, and it is shown on early celestial charts as centaur with a bow and arrow aimed at the heart of a scorpion (the neighboring constellation Scorpius). The brightest stars of Sagittarius were cataloged by Ptolemy (*c.* AD 100–175) in the *Almagest*.

A large, conspicuous constellation, the brightest stars in Sagittarius are ε (Kaus Australis), magnitude 1.8, σ Sagittarii (Nunki), magnitude 2.1, ζ Sagittarii (Ascella), a very close binary with white (A2) components, magnitudes 3.3 and 3.5 (combined magnitude 2.6), separation 0.2–0.6″, period 21.1 years, and δ Sagittarii (Kaus Media), magnitude 2.7. There are 12 other stars of magnitude 4.0 or brighter. Other interesting stars include β Sagittarii (Arkab), a wide, naked-eye optical double with bluish-white (B9) and pale yellow (F2) components, magnitudes 4.0 and 4.3, the former of which has a white (A5) companion, magnitude 7.2, separation 28.5″, and RY Sagittarii, an R Corona Borealis variable (range 5.8–14.0). Eight of the brighter stars form an asterism known as 'the Teapot': δ, ε, ζ and φ represent the body, σ and τ the handle, γ the tip of the spout, and λ the top of the domed lid.

The Milky Way passes through the western half of the constellation, which lies in the direction of the center of the Galaxy. It is brightest just to the north of γ Sagittarii, where it is known as the Great Sagittarius Star Cloud. Among the many star clusters and nebulae are the open clusters M25 (IC 4725), which contains more than 30 stars fainter than sixth magnitude (including the Cepheid variable U Sagittarii, range 6.28–7.15, period 6.75 days), M21 (NGC 6531), which contains about 70 stars fainter than seventh magnitude, and M23 (NGC 6494), which has about 150 stars fainter than ninth magnitude, the fifth-magnitude globular cluster M22 (NGC 6656), which is the third-brightest in the sky, and the sixth-magnitude emission nebulae M8 (NGC 6523, the Lagoon Nebula), M17 (NGC 6618, the Omega Nebula) and M20 (NGC 6514, the Trifid Nebula). M24, a bright portion of the Milky Way sometimes called the Small Sagittatius Star Cloud, contains the open cluster NGC 6603, which consists of several dozen stars fainter than fourteenth magnitude.

Also in Sagittarius are the Sagittarius Dwarf Galaxy, a dwarf spheroidal galaxy in the Local Group and the closest known satellite of the Milky Way Galaxy, lying about 80 000 light-years from its center, and the strong radio source Sagittarius A, part of which (Sagittarius A*) is believed to lie at the center of our Galaxy.

Sagittarius A

The brightest radio source in the constellation of Sagittarius. Located at the center of the Milky Way Galaxy, at a distance of some 25 000 light-years, Sagittarius A (abbreviation, Sgr A) consists of two principal components, Sgr A East and Sgr A West. Sgr A East, which is a source of synchrotron radiation, appears to be a bubble of ionized gas, possibly a supernova remnant. Embedded within Sgr A West, which is a cloud of hot gas, is an intense, very compact, variable radio source called Sagittarius A* (pronounced 'A-star') that has an angular diameter of less than 0.002 arcsec. At the distance of the galactic center, this angular size corresponds to a linear diameter of less than 15 astronomical units (smaller than the diameter of the orbit of the planet Saturn).

Sgr A* appears to have no orbital motion and to be completely stationary. It is therefore believed to mark the exact center of the Galaxy. It lies at the center of a three-armed mini-spiral of hot, ionized gas, some 10 light-years in diameter. The orbital velocities of gas clouds close to the galactic center imply that some 6 million solar masses must lie within a light-year of the galactic center. Since infrared observations imply that stars contribute only about 3 million solar masses to that total, many astronomers contend that the residual 3 million solar masses is contained in a central black hole and that the underlying energy source for Sgr A* is a disk of hot gas swirling round this black hole. Sgr A*, then, appears to be similar in nature to an active galactic nucleus, though on a smaller and less energetic scale.

In 2001, NASA's Chandra X-ray Observatory, detected a sudden x-ray flare while observing Sgr A*. In a few minutes, the source brightened dramatically, eventually reaching a level 45 times brighter than before the flare. After about three hours, the x-ray intensity rapidly declined to the pre-flare level. The rapid rise and fall of the x-rays from this outburst are compelling evidence that the x-ray emission is coming from matter falling into a supermassive black hole. Given the extremely accurate position, it is highly unlikely that the flare is due to an unrelated contaminating source such as an x-ray binary system.

Sagittarius Dwarf Galaxy

The Sagittarius DWARF GALAXY is the closest member of the Milky Way's entourage of satellite galaxies. Discovered by chance in 1994, its presence had previously been overlooked because it is largely hidden by the most crowded regions of our own Galaxy with which it is merging.

Position and morphology

Despite being located at a mere 16 kpc behind the GALACTIC BULGE (see figure 1), and 6 kpc below the Galactic disk, the determination of the morphology of this object has been complicated by its unfavorable position. For this reason, the inferred geometrical picture is somewhat sketchy, especially at Galactic latitudes $b > -10^\circ$ where a large fraction of the dwarf remains hidden behind the Galactic disk (and is revealed in those fields only by number counts of RR Lyrae variables). The Sagittarius dwarf galaxy appears to be a prolate body with axis ratios ∼3:1:1, with its longest dimension extending some 10 kpc in the direction perpendicular to the GALACTIC PLANE. It is assumed that the center of this dwarf galaxy is coincident with the region of highest stellar surface density, which is found at Galactic coordinates $\ell = 5^\circ$, $b = -14.5^\circ$, coincident with the massive GLOBULAR CLUSTER M54. At distances greater than 5 kpc from this center, a very low surface brightness stellar stream has been detected. Because of its irregular structure, it is difficult to estimate the total luminosity of the dwarf; an upper limit from integrating the surface brightness profile (given a simple model of its structure) is $5.8 \times 10^7 L_\odot$.

Its present proximity to the Galactic center must induce huge tidal stresses on the dwarf; this ongoing tidal disruption is expected to lead to its destruction, so its stars and globular clusters will eventually become dispersed and assimilated into the Milky Way halo. Modern GALAXY FORMATION simulations suggest that large galaxies like the Milky Way formed through the repeated ACCRETION of many small galaxies; the existence of the Sagittarius dwarf provides striking evidence that the Milky Way is still growing in the way predicted by such theories. Thus, this dwarf galaxy is perhaps a prime, and it is certainly the closest, example of a small galactic building block, as envisaged in this currently popular picture of hierarchical structure formation. One of the motivations for its study is that this may shed light on the hypothesized population of primordial galaxies that merged to form the Milky Way.

Stellar populations

This dwarf galaxy contains a mix of STELLAR POPULATIONS ranging from intermediate-age stars (given the presence of carbon stars) to old stars (some RR Lyraes are observed), with the dominant stellar population being 10–14 billion years old. It also contains four globular clusters (M54, Ter 7, Ter 8 and Arp 2) which also display an age spread, with Ter 8 being as old as the oldest Galactic halo clusters. The mean chemical abundance lies between [Fe/H] = −0.8 and [Fe/H] = −1.2, while the full abundance range observed covers $\gtrsim$1 dex around this mean.

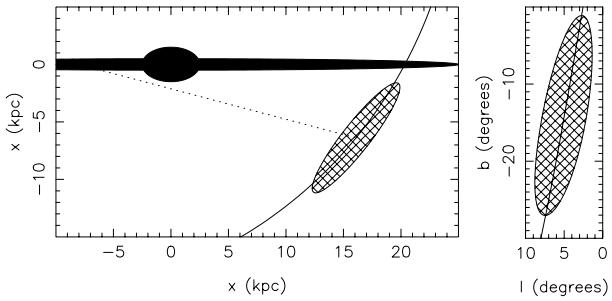

Figure 1. Schematic diagrams showing the position of the Sagittarius dwarf in relation to the Galaxy. In both diagrams, the orbital path of the dwarf is indicated with a solid curve. The left-hand panel is in the x–z plane of the Galaxy. The line of sight from the Sun to the center of the dwarf is marked with a dotted line. The right-hand panel shows the projection of Sagittarius dwarf on the sky.

Kinematics

The RADIAL VELOCITY of the central parts of the Sagittarius dwarf galaxy is $v_r = 171 \pm 1$ km s^{-1}, (after subtraction of the solar motion around the Galactic center). Normally, this would be almost all the kinematic information one could measure from such a system; however, as this galaxy is so close, it is also possible to deduce the transverse motion by measuring its PROPER MOTION. Several numerical studies have shown that dwarf satellite galaxies become elongated in the tidal field of their massive companion. The elongation, it transpires, always points parallel to the plane of the dwarf's orbit. Since the Sagittarius dwarf is almost directly behind the Galactic center, as viewed from Earth, the projected elongation must be aligned with the proper motion vector (and the projection of the orbit) to very good approximation. Given that the Sagittarius dwarf is elongated perpendicular to the Galactic plane, these considerations indicate that it must be on a nearly polar orbit. Proper motion measurements deduced from Schmidt plates show that it has a transverse motion (along the major axis direction) of $v_\perp = 250 \pm 90$ km s^{-1}, and that it is moving northwards.

Orbit and survival

With the above measurements of the three-dimensional position and three-dimensional velocity of the dwarf galaxy, it is possible to calculate its orbit around the Galaxy, assuming a model for the gravitational potential of the Milky Way. Taking a standard Galaxy model, with a double-exponential disk, and a spherical halo giving rise to an asymptotically flat rotation curve ($v_{\rm cir} = 220$ km s^{-1}), the period of the orbit is 0.7 Gyr, and the peri- and apogalactic distances are, respectively, ∼12 kpc and ∼60 kpc. This means that the Sagittarius dwarf galaxy is on a collision course with the disk of the Milky Way that

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

will bring the two galaxies into contact within 25 million years.

Given the age of its dominant stellar component, this orbit implies that the Sagittarius dwarf has had many (more than 10) close interactions with the Milky Way during its lifetime. This turns out to be a very interesting constraint. Numerical N-body simulations show that the tidal stresses on the dwarf are so large each time it passes close to the Milky Way that it should have been destroyed after just a few ($\sim$2) close approaches to the Galaxy, and so it is very surprising that it has survived until the present day. A self-consistent solution to the present existence of the dwarf can be obtained if the observed stars do not trace the underlying mass. That is, the tidal disruption of the Sagittarius dwarf can be impeded if the stellar component of the dwarf galaxy is enveloped in a halo of DARK MATTER, which has a mass profile such that dark matter density is a factor of 2–3 larger than the mean Galactic density interior to its perigalacticon distance. To be consistent with the observed low velocity dispersion of the stellar component embedded therein, the core radius of the dark halo would have to extend out to the photometric edge of the system. The total mass of stars and dark matter is then $M > 5 \times 10^8 M_\odot$. With this model, the escape velocity from the center of the Sagittarius dwarf is substantial, $v_e = 90 \mathrm{km\,s^{-1}}$, which would help to explain the observed wide abundance range. The only alternative to this dark matter halo scenario is if the Sagittarius dwarf was deflected from a previously longer period orbit into its current short period orbit by a close encounter with another satellite, perhaps the LARGE MAGELLANIC CLOUD (LMC); however, the chances of such a 'bull's-eye' collision are small.

It is interesting to note that all of the numerical simulations of the disruption of this dwarf galaxy give rise to streams of tidally disrupted material that follow the orbital path of the main body of the dwarf quite closely. The disrupted fraction can be significant, so one may expect to find a sizeable fraction of the stellar component of the Sagittarius dwarf spheroidal, including perhaps several globular clusters, stretching along the locus of the orbit around the sky. It will be very fruitful to detect such material, as the kinematics of the stream will provide a very sensitive test of the Galactic potential gradients.

Interaction with the Milky Way

The models of the Sagittarius dwarf galaxy that are designed to reduce tidal disruption have sufficient mass to affect the structure of the Milky Way. Hydrodynamical calculations undertaken to simulate the collisional interaction between the Sagittarius dwarf and the Galactic outer H I disk show that a significant distortion of the Galactic H I disk will be induced by the collision if the mass of the dwarf exceeds $\sim 10^9 M_\odot$. Indeed, if $M \gtrsim 10^9 M_\odot$, the tidal forces on the Milky Way due to the Sagittarius dwarf will be substantially larger than those due to the LMC, which has also been invoked as a possible perturber of the H I disk. For model masses $\gtrsim 5 \times 10^9 M_\odot$, prominent spiral arms and a substantial lopsidedness in the outer disk are produced. Furthermore, a noticeable warp-like structure is induced in the disk. It seems that the Sagittarius dwarf may have significantly affected the star formation history and structure of the outer Galaxy.

Much interesting work remains to be done in understanding the chemical evolution of the dwarf (and the outer regions of the Galaxy) and how this is affected by the interaction (see also GALAXIES: INTERACTIONS AND MERGERS). From this, one may gain insights into the chemical evolution of galaxies during a merger event, and in turn about dominant evolutionary processes occurring during hierarchical formation of 'normal'-sized galaxy units.

Saha, Meghnad (1893–1956)

Physicist, born in Seoratali, near Dacca, India, became professor of physics at Calcutta, where he founded the Calcutta Institute of Nuclear Physics, now the Saha Institute. Saha (and Bose) translated several of Einstein's papers from German into English, leading to their greater dissemination, and he worked on the thermal ionization that occurs in the atmosphere of stars. He showed that elements in stars are ionized in relation to their temperature, as described by *Saha's equation*. This work fundamentally underpinned the interpretation of stellar spectra and led to the determination by HENRY RUSSELL of the abundances of the elements.

Sakurai's Object

Sakurai's Object (V4334 Sgr, RA = $17^h\,52^m\,32^s.69$ and Decl. = $-17^\circ\,41'\,07''.7$ at equinox 2000.0) is the central star of a faint PLANETARY NEBULA which experienced a late helium flash at, presumably, the end of 1994. It was discovered by amateur astronomer Yukio Sakurai in February 1996 as a rapidly brightening object, then at the 11th magnitude. It remained bright during two years, before dimming in mid-1998.

Sakurai's Object is the third 'final helium flash' star monitored so far. The first one was V605 Aql whose outburst and subsequent fading occurred during 1919–1923. Its characteristics were very similar to those of Sakurai's Object. The second one, FG SAGITTAE, had a longer evolution time scale. It presumably underwent its final helium flash at the beginning of the 19th century, reached its maximum visual brightness in mid-1970, and faded in 1992.

Final helium flash stars are post-asymptotic giant branch (post-AGB) stars on their way to the WHITE DWARF stage which experience a late thermal instability in their helium burning shell. The blue compact post-AGB star evolves back to a RED GIANT configuration on a time scale of a few years to a few decades. As a result, its effective temperature decreases from above 90 000 K to less than 7000 K, but its bolometric luminosity is expected to remain more or less constant (after a possible rapid initial increase at the onset of outburst). The rapid increase in the visual magnitude by several orders of magnitude then essentially results from the surface color change.

The current evolution of Sakurai's Object on its way back to the red giant configuration is accompanied by a change in its surface chemical composition. Spectroscopic monitoring during 1996 reveals an important decrease of its hydrogen abundance by a factor of ten, while the abundances of some other elements, such as lithium or some elements heavier than iron, have meanwhile increased. The exact internal mixing and NUCLEOSYNTHESIS scenarios responsible for those surface abundance variations are still a matter of debate among astrophysicists, given the complexity of the structural evolution of those stars. In this context, the observed properties of Sakurai's Object offer a unique opportunity to test our understanding of the physical and nucleosynthesis mechanisms at work in such stars. Final helium flash stars may furthermore provide important clues to understand the formation of R CORONAE BOREALIS (R CrB) STARS as well as of some white dwarf stars.

The final helium flash

The rapid evolution of the photometric and spectroscopic properties of Sakurai's Object is currently understood as resulting from the occurrence of a thermal instability in its interior. Such a thermal instability is a well established feature of AGB stars, the progenitors of final helium flash stars. It results from their double burning shell configuration, one of helium capped by one of hydrogen. Those burning shells are very thin, the hydrogen burning shell having about 0.001 solar mass ($M_\odot$) and the helium burning shell about 0.01 $M_\odot$.

During most of the AGB lifetime, the stellar luminosity is supplied by the hydrogen burning shell. The helium synthesized in that burning shell accumulates in the helium burning shell, whose temperature eventually increases until a thermal runaway is triggered. The instability, also called helium flash (not to be confused with the core helium flash which develops in the electron degenerate central regions of low-mass stars at the onset of helium burning), liberates one hundred to one million times the stellar luminosity on a time span of only several tens to hundreds of years. That energy, however, is mainly absorbed by the intershell layers, and affects the surface luminosity only to a factor of two. The intershell layers are thus subject to important thermal and structural readjustments during the after-flash phase. In particular, the convective envelope may penetrate through the now extinct hydrogen burning shell into the C-rich layers, and bring to the surface ashes of helium burning nucleosynthesis. CARBON STARS, for example, are currently understood as resulting from the operation of a series of such dredge-ups.

Those thermal instabilities (also called pulses) occur periodically in AGB stars on a time scale of 10^3 to 10^5 years, depending on the mass of the hydrogen-depleted core. When the star leaves the AGB, it evolves to the white dwarf stage on a time scale comparable to that of the interpulse phase. A 'final' helium flash may occur in that post-AGB stage if the star has not yet sufficiently cooled in the white dwarf configuration at the time the next instability is expected to occur. Current estimations predict the occurrence of such a final instability in about 10% of post-AGB stars.

The detailed structural and chemical evolution of post-AGB stars undergoing a final helium flash is not yet well understood. The current lack of model predictions for such stars is due to the difficulty of modeling adequately the chemical and energetic evolution of their intershell layers. In some cases indeed, such as presumably for Sakurai's Object, the final helium flash is triggered at a late stage of the post-AGB phase, when the star is already fading to the white dwarf stage. In those conditions, the intershell mixing triggered by the helium flash may cross the now almost extinct hydrogen burning shell and reach the envelope. Hydrogen is consequently mixed from the surface down to the high temperatures characterizing the helium burning shell, and burns. The observed depletion of hydrogen at the surface of Sakurai's Object may result from the operation of such a scenario.

The planetary nebula

The faint planetary nebula observed around Sakurai's Object supports the idea of it being a final helium flash star. The measurement of the size of the planetary nebula ($\sim 40''$) and of its expansion velocity ($\sim 31\,\mathrm{km\,s^{-1}}$) can lead to the determination of its age, or in other words of the time

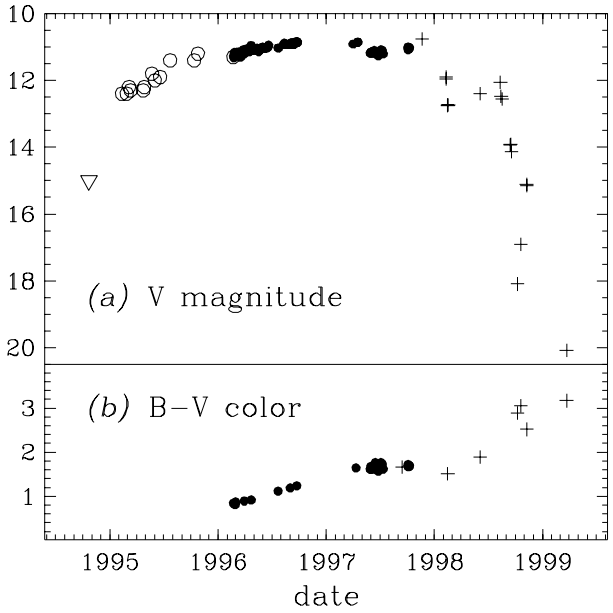

Figure 1. Evolution of the V magnitude of Sakurai's Object from 1995 to 1999. Open symbols refer to pre-discovery estimates from Takamizawa's photographic plates (http://www.kusastro.kyoto-u.ac.jp/vsnet), the triangle representing an upper limit. Filled circles are observations published in *Astron. J.* **114** 1657, and in *Astron. Lett.* **24** 248. Plus signs are measurements reported in several circulars of the International Astronomical Union.

elapsed since Sakurai's Object left the AGB, if we know the distance to the object. Based on an estimation of the absolute stellar magnitude from photoionization models of the nebula, a distance of five to eight kiloparsecs is found (see also next section). The planetary nebula would then have a radius of ~ 0.7 pc and an age of $\sim 24\,000$ years. This age is consistent with the time necessary for a post-AGB star to evolve from the tip of the AGB to the high surface temperatures ($> 50\,000$ K) required to ionize the nebula.

It is worth mentioning that the planetary nebula around Sakurai's Object was in fact searched for, and discovered, only after the object brightened, guided by the remarkable similarity of Sakurai's Object to V605 Aql, the central star of the planetary nebula A 58.

Luminosity and color variations

The light curve of Sakurai's Object in the V band is shown in figure 1(a). It has been followed in detail since Sakurai's discovery in 1996 (filled circles in the figure), and reveals a continuous brightening of the star by about half a magnitude over the following 18 months. Superimposed on that steady visual magnitude increase, small amplitude variations ($\lesssim$ 0.1 mag) are further detected on a time scale of few to 60 days (not visible in the figure). Those variabilities may be related to stellar pulsation modes triggered by the classical κ-mechanism acting on the partial ionization zones in the envelope of Sakurai's Object.

When was the outburst of Sakurai's Object initiated? The answer requires further information on the light curve of that object prior to Sakurai's discovery. Fortunately, photographic records taken by Takamizawa during 1995 enable one to extend the light curve in some detail up to one year prior to its discovery (open circles in figure 1(a). They confirm the general picture of the star's rapid brightening. Moreover, the analysis of photographic plates in 1994 puts a lower limit on its visual magnitude (upper limit on its brightness) of 15 mag (open triangle in the figure), and locates the start of the outburst at the end of 1994.

The rapid increase in visual magnitude after the outburst, by four stellar magnitudes over 500 days (figure 1(a)), is compatible with the picture of an expanding photosphere surrounding an object of constant luminosity. The radial expansion rate of the photosphere is estimated to be 0.05 solar radius ($R_\odot$) per day (i.e. 1500 km h^{-1}) at burst, and twice this value in 1996. The expansion of the compact post-AGB star to a giant configuration is accompanied by a concomitant cooling of its photosphere. This cooling is attested by the change in the B − V color index as shown in figure 1(b). Photometric and spectroscopic measurements lead to effective temperatures of 8000 and 7000 K at the beginning and end of 1996, respectively, to be compared with an estimated temperature higher than 90 000 K before burst.

A rapid increase of the luminosity may have occurred at the onset of the flash in 1995. The analysis of the remnant ionization of the planetary nebula around Sakurai's Object indeed suggests that the luminosity of the pre-flash central object, then close to a white dwarf's configuration, was of the order of one hundred times the solar luminosity ($L_\odot$). It must have rapidly reached 5000–10 000 $L_\odot$ after the outburst, and kept this value, to within a factor of three, during the subsequent expansion phase. The increase in the visual magnitude from 1996 to 1998 then mainly results from the change in color during that period.

Knowledge of the distance to Sakurai's Object would be an important ingredient in estimating its physical characteristics such as its absolute magnitude. Unfortunately, such information is difficult to derive from current observations. Several techniques have been applied to Sakurai's Object, such as those based on its PROPER MOTION in the Galaxy, on the degree of interstellar extinction suffered by the light during its travel from the star to us, on the comparison of its luminosity with that of V605 Aql, or on the comparison of the observed characteristics of the star and of its nebula with those predicted by model calculations. Most of them lead to a distance estimation between 5 and 8 kiloparsecs, the latter value putting Sakurai's Object in the bulge of our Galaxy. But even those values are still uncertain (a value of 1.1 kpc has even been derived from the extinction method), and illustrate the difficulty of deriving accurate individual distances in astronomy.

Comparison of the observed characteristics of Sakurai's Object with the few available final-helium flash model predictions suggests a stellar mass between 0.7 and 0.8 $M_\odot$, a luminosity between 5000 and 15 000 $L_\odot$, and a

Dirac House, Temple Back, Bristol, BS1 6BE, UK

radius between 50 and 100 $R_\odot$. Those data, however, still need to be confirmed by adequate helium flash model predictions.

Sakurai's Object dimmed dramatically, though irregularly, from 1998 onward (plus signs in the figure), with M_v increasing above 20 in 1999. The rapid fading is very similar to that observed in V605 Aql at the beginning of this century. It is attributed to the formation of dust in an extended shell around the star. This is attested to by the detection, already from mid 1997, of the CN and C_2 bands in the spectrum of Sakurai's Object, and of a strong excess in the infrared emission. Photometry taken by the Infrared Space Observatory (ISO) in 1997 indeed showed an increase of the flux in the range 4–15 μm by a factor of about ten. The inferred mass loss from Sakurai's Object reaches $10^{-7} M_\odot$/yr. The extensive dust formation is very similar to that seen in R CrB stars.

Surface abundances

Most of the data currently available in the literature on the surface abundances of Sakurai's Object were obtained in 1996. Sakurai's Object is slightly metal-poor, with an iron mass fraction 0.2 to 1 dex below solar, and displays peculiar chemical composition compared to normal red giants. In general, the observed abundances confirm the double shell structure characteristic of AGB stars and the dredge-up scenario.

Sakurai's Object is first of all enriched in carbon, with [C/Fe] $\simeq$ 2.3 (the notation [X] stands for $\log X/X_\odot$, where $X_\odot$ is the solar abundance). The carbon enrichment can easily be explained by the operation of one or more dredge-up episodes when the star was on the AGB, the carbon being produced in the helium burning shell. Such a scenario is probably also the origin of the high oxygen ([O/Fe] $\simeq$ 1.5), sodium ([Na/Fe] $\simeq$ 1.4), neon ([Ne/Fe] $\simeq$ 2.4) and aluminum ([Al/Fe] $\simeq$ 1.1) abundances. Oxygen is produced directly in the helium burning shell, and sodium could be produced by successive dredge-up and hydrogen burning sequences. Reliable chemical abundance predictions, however, are still lacking and prevent a quantitative comparison with the abundances observed in Sakurai's Object.

Sakurai's Object also reveals an important nitrogen abundance enhancement ([N/Fe] $\simeq$ 2.2), which must have its origin in the CNO cycles of hydrogen burning during the AGB phase. In order to lead to significant nitrogen production, however, the synthesis of nitrogen must have occurred directly in the convective envelope, requiring temperatures at the base of the envelope exceeding 50×10^6 K. This scenario is further supported by the low $^{12}C/^{13}C$ isotopic abundance ratio of 1.5–5 measured in Sakurai's Object, which essentially points to the equilibrium value of the CNO cycle.

A similar constraint is provided by the measurement of high lithium abundances in Sakurai's Object. The most remarkable feature, however, is the rapid increase currently observed in the Li abundance, by 0.6 dex within four months in 1996. The scenario responsible for such an increase invokes the production of beryllium in the hot (temperatures above 50×10^6 K) bottom layers of the envelope and its convective transport to the surface, where it transforms to lithium by electron capture. Such a scenario requires thus a subtle coupling of mixing and nucleosynthesis, which must currently be at work in Sakurai's Object.

Rapid abundance alterations are also recorded for other elements such as Sc, Ti, Cr, Zn, Rb and Y. The abundances of those heavy elements have indeed significantly increased by 0.6 to 1 dex between April and October 1996. Those particular elements are synthesized by neutron capture reactions (the so-called s-process, which is also responsible for a similar abundance pattern of heavy elements in S and C stars). The production of the required neutrons in the helium burning shell, however, imposes specific constraints on stellar models which are still matter of research. In this respect too, Sakurai's Object provides a unique opportunity to test our understanding of those objects in particular, and of AGB stars in general.

Last but not least, the hydrogen abundance of Sakurai's Object was observed to decrease rapidly in 1996. In April of that year, it was already one hundred times lower than the hydrogen abundance in the Sun, and it decreased by another factor of ten during the next six months. The abundance pattern of Sakurai's Object is actually very similar to those of R CrB stars. Those stars are characterized by very low hydrogen abundances and by unpredictable visual dimming effects. Both of those features are now displayed by Sakurai's Object. We may thus be witnessing in Sakurai's Object the birth of a new R CrB star, providing a clue to the formation of at least a fraction of those stars.

Bibliography

Given the recent discovery of Sakurai's Object, further information should be sought in papers published in international astrophysical journals. The interested reader may look to the first papers on this object:

Salpeter, Edwin Ernest (1924–)

Nuclear astrophysicist, born in Austria, emigrated to Australia and was educated in Sydney, and at Birmingham University. Became professor at Cornell University. Worked with HANS BETHE on atomic physics, and in 1951 explained the 'triple alpha' reaction, also called the *Salpeter process*, which in red giant stars makes carbon-12 from three helium nuclei. This led him to investigate stellar evolution, and, from this theory and observations of stars of different luminosities, he worked back to the initial mass function, i.e. the rate of formation of stars of different mass in the Galaxy, now known as the *Salpeter function*. This important concept identifies a target for theories of star formation to explain.

San Fernando Observatory

The San Fernando Observatory is located on the north side of the San Fernando Valley, approximately 30 miles northwest of downtown Los Angeles. It was built by the Aerospace Corporation in 1969 and donated to the California State University, Northridge, in 1976.

The observatory has a variety of modern instruments. The main instrument is a 61/28 cm aperture vacuum telescope feeding a vacuum spectroheliograph. At present, the spectroheliograph is configured as a Video Spectro-Spectraheliograph (VSSHG). After the VSSHG completes a scan of an active region, the output consists of two data cubes, each of which has solar north–south and east–west as the x- and y-axes and wavelength as the z-axis. The two cubes have orthogonal polarizations.

Other instruments are contained in the Little Dome. These are the full disk photometric telescopes: the Cartesian Full Disk Telescope no. 1 (CFDT1); Cartesian Full Disk Telescope no. 2 (CFDT2); and the Rotating Full Disk Photometer (RFDP). The CFDT telescopes obtain daily full-disk photometric images of the Sun.

A separate 10 m high tower contains a folded 15 cm refracting telescope designed to study individual active regions at the diffraction limit of 1 arcsec.

Research specialties are the measurement on a daily basis of solar variability due to sunspots and faculae and the study of the eruption and disappearance of solar magnetic flux, particularly in active regions.

Support comes primarily from the federal government, both from the National Science Foundation and from the National Aeronautics and Space Administration. The University provides some support for upkeep and maintenance.

Sandage, Allan Rex (1926–)

Astronomer, born in Iowa City, IA. Worked with WALTER BAADE and EDWIN HUBBLE, and became professor at Mount Wilson and Palomar observatories. His research has focused on the biggest problems in cosmology. He determined the ages of the stars in globular clusters (the oldest objects known, apart from the chemical elements). In 1960, with JESSE GREENSTEIN, he identified the radio source 3C48 as a blue star with an unusual, unidentifiable spectrum. After MAARTEN SCHMIDT'S breakthrough recognition of the nature of 3C273, this discovery by Sandage was recognized as the first quasar. Discovering many more quasars, Sandage worked on their properties. Realizing that the key question in cosmology was (and perhaps still is) the age and distance scale of the universe, he invested his career in the calibration of 'standard candles' (Cepheids, supernovae, ...), used to determine the distances of remote galaxies, most recently using the Hubble Space Telescope, for which he prepared an influential preparatory atlas of galaxies. This has led him to progressively more accurate values of the Hubble constant and the deceleration parameter of the universe.

Saros

The eclipse cycle of 18 years 11.3 days, after which the pattern of eclipses which occurred at the beginning of the cycle is quite closely repeated. The cycle was known in ancient Greek times and was used for eclipse prediction. The repetition is not perfect, however, as changes in the pattern increase with time. The cycle is almost exactly equal to the time taken for the nodes of the Moon's orbit to make a complete circle of the Earth. After one cycle, the Sun, Moon, and nodes return almost to the same relative positions and it is the alignment of these which determines the occurrence of eclipses. As the relative positions of the bodies are slightly changed after each saros, an eclipse cycle ends after a number of saroses—approximately 71 for solar eclipses and 48 for lunar. Each saros contains about 43 solar and 28 lunar eclipses.

Satellite (Natural)

In its most general sense, any celestial object in orbit around a similar larger object. Thus, for example, the Magellanic Clouds are satellite galaxies of our own Milky Way galaxy. Without qualification, the term is used to mean a body in orbit around a planet; an alternative term is *moon*. The term *natural satellite* distinguishes these bodies from *artificial satellites*—spacecraft placed in orbit around the Earth or another celestial body.

In the solar system, all the major planets except Mercury and Venus possess one or more satellites, and many of these are planetary bodies in their own right. Jupiter's largest satellite, Ganymede, is bigger than Mercury, and seven solar system satellites are larger than Pluto. Saturn's largest satellite, Titan, is the only one to possess a substantial atmosphere, with a surface pressure one and a half times the Earth's; other large satellites are known to have rarefied atmospheres. Many show signs of present or past geological activity, and Jupiter's Io is the most active body of all the planets and satellites in the solar system. The giant planets possess the lion's share of the major planets' complement of satellites: 60 of the 64 known for certain by 1999. Saturn and Uranus have the most, each with 18 confirmed (other minor satellites of Saturn and Uranus are suspected, and there are almost certainly minor satellites of the other giant planets awaiting discovery). A few asteroids, including (45) Eugenia and (243) Ida, have small satellites which have been directly imaged optically, while a number of others, including (4179) Toutatis, have been shown by techniques such as radar imaging to consist of two objects in close contact. The nucleus of Comet Hale–Bopp was found to have a small satellite in orbit around it.

Planetary satellites may be categorized as *regular* or *irregular*, according to their orbit. Regular satellites are those in direct orbits, in the direction of the planet's axial rotation, which are of low eccentricity and orbital inclination. Irregular satellites tend to be smaller, and follow orbits which are retrograde, or of high inclination, or show any combination of these properties. Whether satellites are regular or irregular also reflects their origin. Large regular satellites such as the Galilean satellites of Jupiter are believed to have condensed out of the same part of the solar nebula as their parent planet, from a *protosatellite disk*. The small and medium-sized regular satellites of Saturn are most likely collisional fragments of larger bodies. Uranus's satellite system is inferred to have been formed by the impact that is surmised to have given the planet its extreme axial tilt. Likewise, the Earth's Moon is believed to have accreted from the debris of a giant impact. Irregular satellites, such as Neptune's Triton, and the outermost satellites of the other three giant planets, were acquired by gravitational capture. Triton is probably a captured Kuiper Belt object; the others are probably captured asteroids or extinct comet nuclei. Jupiter's outer satellites fall into two groups, each representing a different capture mechanism.

Saturn

Without its rings, Saturn looks like a pale JUPITER, with striking similarities to its giant sister (figure 1). As planetologists became more familiar with the structure of both planets, when they measured their thermal structure, composition and the zonal winds, this similarity appeared still more evident. However, important differences have been revealed as well. On the contrary, the other giants, URANUS and NEPTUNE, are more different, with atmospheric temperatures low enough to condense methane. It is therefore natural to list, as a starting point for the studies of Saturn's atmosphere, the similarities and differences between Saturn and Jupiter, each one telling us more about the formation of planets in the external solar system. As a model, Jupiter is better understood than Saturn, because of proximity and because it was visited by an atmospheric probe in 1995. As expected, the Jupiter results would benefit the Saturnian studies, as illustrated by examples given below.

Historical observations

The observations of the disk of Saturn at the beginning of telescopic observations, in the 17th century, were rendered difficult by the presence of the rings, which perturbed even simple observations of the shape of the planet (see SATURN: RINGS). The flattening of the planet was measured by William Herschel only in 1789, when the rings were observed on their edge, a configuration repeated only every 14 yr. The fainter contrast of atmospheric features, compared with Jupiter, precluded also the observation of any atmospheric structure before 1676, when Gian Domenico Cassini discovered the existence of an equatorial belt. The period of rotation was accurately measured later in 1790 by Herschel. Accurate telescopic observations on a regular basis have now permitted the constitution of a planetary database, used for the study of long-term evolution of atmospheric features, such as the global storms discussed below. However, only few individual atmospheric spots were observed before the space age. After the *Pioneer 11* observations in 1979, which gave important information about thermal structure and magnetospheric emissions, the *Voyager* observations in 1980–1981 provided the first accurate tracking of individual spots in the atmosphere, and the differential rotation of Saturn could be measured for the first time. The development of ultrasensitive charged coupled devices has since permitted a continuous monitoring of Saturn's long-lived individual spots with ground-based telescopes and the Hubble Space Telescope.

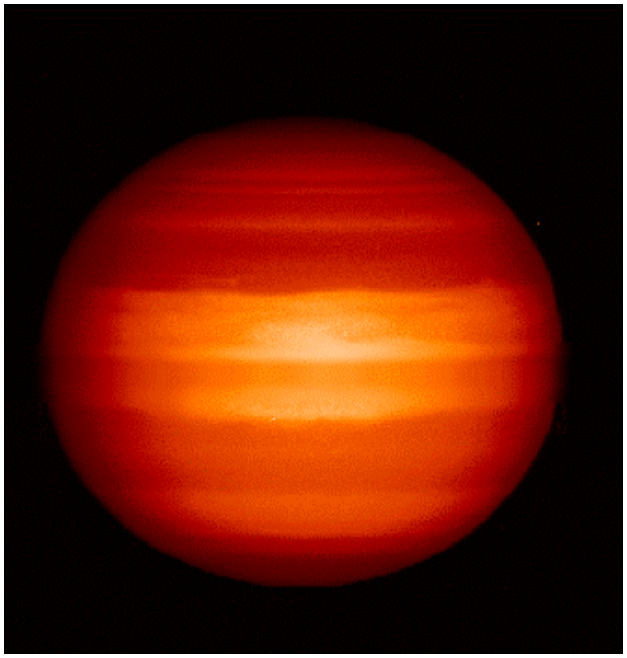

Figure 1. This unusual view of Saturn has been processed from an image taken by the HST Wide Field Planetary Camera (STScI-PRC96-16) on 17 November 1995. The rings have been artificially erased, and the equatorial region has been filled to eliminate all trace of the rings. Credit NASA.

Description

The physical and orbital parameters of Saturn are given in table 1, with comparison with Jupiter. These parameters give a first constraint to the models of formation of Saturn. Such models can predict the thermal evolution of a giant planet, given its initial mass and composition. In the list, the effective temperature is an important parameter, as it is related to the energy budget of the planet. It can be defined as the temperature of

Table 1. Jupiter and Saturn, the sister planets.

	Jupiter	Saturn
Revolution period	11.9 yr	29.6yr
Mass	1.899×10^{27} kg	0.568×10^{27}
Equatorial radius (at 1 bar)	71 492 km	60 268 km
Flattening	6.48%	9.80%
Rotation period (magnetic field)	9 h 50 mn 30 s	10 h 39 mn 22 s
Atmospheric He mass fraction (Y)	0.234[a]	0.06[b]
Mean density	1.33 g cm^{-3}	0.70 g cm^{-3}
Equilibrium temperature	109.5 K	82.4 K
Effective temperature	124.4 K	95.0 K
Emitted/received energy	1.67	1.78
Gravity at the equator (1 bar)	22.9 m s^{-2}	9.1 m s^{-2}
Obliquity	3°	27°

and Institute of Physics Publishing 2001

a black body that would radiate on average the same amount of energy per surface unit as the planet itself. The effective temperature is higher than the equilibrium temperature, the temperature of a planet heated solely by the Sun. An important result of the Pioneer and Voyager missions was an accurate measurement of the radiative budget of Saturn and of the excess energy due to an internal source. In the case of Saturn, the internal heat magnitude is found to be comparable with the amount absorbed from the Sun.

The important fact that both Jupiter and Saturn emit more energy to space than received from the Sun has implications for their internal structure. The excess energy can come either from a residual contraction of the planet, transforming gravitational energy to heat, which is in turn radiated to the space, or from a compositional fractionation. In the latter case, some heavy elements, especially helium, fall to Saturn's core, again dissipating the gravitational energy. The last process cannot take place within the upper fluid atmosphere, where the gas or liquid phase of normal hydrogen is uniformly mixed with other gases. At high pressures (3–5 Mb) in the interior of Saturn, hydrogen changes to a metallic state, helium condenses to a liquid state and fractionates from the former.

The fact that, despite a lower mass, the diameter of Saturn is close to that of Jupiter is also understandable from the internal structure of the planet. The thermal history of Saturn is different from that of Jupiter, owing to the different mass and distance to the Sun. The difference in the abundance of helium between Saturn and Jupiter, as measured by Voyager, can be understood if the separation of helium took place earlier on Saturn than on Jupiter. Some recent measurements have questioned the accuracy of the helium abundance of Saturn. New estimates give a helium abundance closer to the original H/He of the solar nebula, although still lower than that on Jupiter. The question of the internal structure of the giant planets is therefore still largely uncertain, and further measurements are highly desirable to improve the models.

Planetary formation

The formation of a giant planet from the original solar nebula is described by modeling the accretion mechanisms in the first stages of the solar system. The scenario has been assembled from various constraints, in particular on the composition, internal structure and the shape. Many details remain to be refined, but a general agreement between various models is as follows.

The first step begins with the ACCRETION of a core of icy PLANETESIMALS and grains of dust up to about 10 Earth masses, with a composition thought to be similar to that of the KUIPER BELT objects, which form a belt of icy asteroids beyond the orbit of Neptune, or to some comets that are observed in the inner solar system. With a core of this size, the gas of the solar nebula itself begins to be accreted in the protoplanet, resulting in a fast growth of the planet until its final mass, reached when all the available material in the vicinity of the core has been accreted. The entire process could be completed in only a few million years. This scenario has been confirmed by the measurements of the heavy elements on Jupiter made by the GALILEO probe. Furthermore, the similarity between Saturn and Jupiter suggests a similar formation scenario for Saturn also. In the case of Jupiter, the measured composition gives a comparable enhancement for the elements C, S, N, Ar, Kr and Xe compared with the solar nebula. This result rules out older models that propose homogeneous accretion in the solar nebula, which would imply a global composition of the planets similar to the solar nebula. It also rules out models involving planetesimals which would have experienced a differentiation in their ice contents, the most volatile compounds, such as nitrogen, being lost during thermal processing of pristine ices. Once formed, the new planet slowly cools down, and some constituents, such as helium, begin to sediment when the temperature is cold enough. The timeline of the evolution of Saturn will be dependent on the convection in the interior and the heat release from the interior. A determination of its present state, in particular the He/H_2 ratio, will therefore help to constrain the models of evolution.

Interior

The interior of Saturn can be probed indirectly by measurements of the gravity field, the composition, thermal structure, heat flow and magnetic field. The models of the interior are based on the high-pressure thermodynamics of hydrogen–helium mixtures, which can be computed from first principles of physics, but unfortunately only with large uncertainties. Laboratory experiments are necessary to explore this poorly understood high-pressures physics. A *terra incognita* is the region of metallic hydrogen, a still hypothetical phase of high-pressure hydrogen where H_2 molecules can exchange their electrons becoming electrically conductive. Unfortunately, the experiments hardly reach the margin of this region. The interior of Saturn exhibits very large pressures, ranging between 0 and almost 50 Mbar (1 Mbar is one million Earth atmospheric pressures) at the center, and temperatures rising to about 10 000 K. Let us imagine a journey towards the interior of Saturn. Starting from the external layers, we encounter first the boundary between metallic hydrogen and molecular hydrogen envelope at about 2.8 Mbar, at about half the radius of Saturn. Is the change in density at the boundary large enough to generate giant waves, like at the surface of a monstrous ocean? Nobody knows. Deeper in the planet we find a boundary between an ice core, enriched in He, and the hydrogen-rich envelope at about three-quarters of the way into Saturn's interior.

Dirac House, Temple Back, Bristol, BS1 6BE, UK

Finally, a rock core is expected to be located at 0.88 of Saturn's radius towards the centre. The mass of this central core is estimated at between 0 and 10 Earth masses, and current models do not even rule out the possibility that it could be totally absent, the heavy elements being diluted in the other parts of the planet, although this case is not considered as the most probable.

The separation of helium from hydrogen takes place in the region where helium condenses to liquid and hydrogen turns to metallic hydrogen, according to the theoretical models of the equation of state of hydrogen. The upper atmosphere also becomes depleted in helium and relatively enriched in hydrogen, and the fall of helium droplets into the interior releases gravitational energy, contributing partly to the source of internal heat. On Jupiter the separation process started later than on Saturn, according to the model, because of the higher temperatures experienced at Jupiter. Effectively, the depletion of helium measured by Galileo is only marginally smaller than the solar nebula abundance. On Saturn, there has been a recent reevaluation of the He/H_2 ratio; new measurements seem to indicate less depletion in helium than the first Voyager measurements, listed in table 1, but they still show a substantial depletion.

Thermal structure

The thermal structure of Saturn is again very similar to that of Jupiter, with differences attributable to the larger distance to the Sun. Several techniques are used to remotely retrieve the thermal profile of Saturn. One is the use of a stellar or solar OCCULTATION, when a star (or the Sun) is eclipsed behind Saturn: the extinction curve of the light when observed through denser and denser atmospheric levels gives a measure of the vertical variation of density. From the density curve, one can retrieve the temperature with height, or pressure in the upper atmosphere. Another technique is the inversion of infrared spectra where a well-known constituent, such as CH_4, absorbs with spectral characteristics depending on the temperature. Combining these techniques, together with infrared and radio science data, it has been possible to probe the atmosphere in the pressure range from 1 bar to 0.001 mbar. An extrapolation of the profiles extends the thermal profiles to lower or higher atmospheric regions.

Like the atmosphere of Jupiter, Saturn's upper atmosphere can be separated into two domains, with opposite temperature gradients: the troposphere, where temperature is increasing downwards, and the stratosphere, with temperature increasing upwards (see PLANETARY ATMOSPHERES). The boundary between them is called the tropopause, a layer located between 60 and 100 mbar, at a temperature of 80 K (or –193 °C). The presence of a minimum temperature in the atmosphere at the tropopause is due to the absorption of solar energy by methane in the upper atmosphere, which heats the upper stratospheric layers.

The heat is dissipated mainly by two processes in a planetary atmosphere: convection transports heat through atmospheric turbulent motions and radiation transports heat by the thermal (mainly infrared) radiation through the atmosphere, if it is transparent enough. To the first approximation, convection in the troposphere and radiation in the stratosphere are the dominant mechanisms of heat transport. In the troposphere, convection maintains a constant gradient in the temperature, with a regular increase of about 0.8 K km^{-1} below the clouds. In the stratosphere, the atmosphere is stable against convection, since the upper layers are hotter than the lower, and heat is transported by radiation (or also by more complex dynamical processes like atmospheric waves, as discussed below).

The reality could be more complex than described here. In particular, the presence of a radiative layer, below the clouds, within the tropopause has been recently predicted: the presence of such a layer, where the atmosphere would be stable against convection in contradiction to the above description, as in the stratosphere, would have important implications for the transport of heat from the interior of Jupiter or Saturn to the observable layers. A better knowledge of the external composition, cloud structure and the radiative opacity of the atmosphere will be needed to complete such models.

The upper atmosphere of Saturn is dominated by other processes. A large temperature increase is observed in the upper atmosphere, at the microbar level and above, with the temperature reaching a constant value at high altitude, called the exospheric temperature. Two main mechanisms could be responsible for this heating, which is also observed in the stratosphere and thermosphere of other giant planets.

An explanation could be the deposition of energy by charged particles from the magnetosphere (see SATURN: MAGNETOSPHERE). In contrast to Jupiter, in the case of Saturn the deposited energy seems too low to explain the high exospheric temperature. It has been proposed that the ionosphere could also be traversed by high electrical currents whose dissipation would heat the atmosphere. An internal origin of the heating is also possible. Heating by internal waves, produced in the deep atmosphere and dissipating their energy in the upper atmospheric layers of the order of 1 μbar, has been proposed. This model is very attractive, as it also takes into account several measurements of the turbulence in the giant planets.

Composition

The general composition of Saturn is given in table 2, where the measurements have been taken from various ground-based and space observations, in particular from Voyager and ISO spacecraft. Even though compounds

Table 2. Composition of Saturn's atmosphere.

Molecule	Mole fraction relative to H_2
Hydrogen (H_2)	1
Helium (He)	0.034
Methane (CH_4)	4.5×10^{-3}
Ammonia[a] (NH_3)	$(1–6) \times 10^{-4}$
Water[a] (H_2O)	Still below the saturation vapor pressure at 3 bar
Phosphine[b] (PH_3)	4.5×10^{-6}
Monodeuterated methane (CH_3D)	3.25×10^{-7}
Carbon monoxide (CO)	1.65×10^{-9}
Arsine[b] (AsH_3)	35×10^{-9}
Germane[b] (GeH_4)	55×10^{-10}
Ethane (C_2H_6)	35×10^{-6} (stratosphere)
Acetylene (C_2H_2)	2.15×10^{-7} (stratosphere)
Carbon dioxide (CO_2)	3×10^{-10} (stratosphere)
Benzene (C_6H_6)	(Stratosphere)
Methyl radical (CH_3)	(Stratosphere)

For species vertically varying by [a] condensation or [b] photochemical destruction, the current estimate of the deep abundance has been listed.
From Atreya *et al* 1999 *Planet. Space Sci*. The abundance measurements are given with very large uncertainty, even for the major constituents (He, CH_4).

heavier than helium constitute less than 0.2% of the atmosphere of Saturn (by volume), they are important in the energy balance of radiation, because hydrogen and helium are poor radiative emittors. Methane, for example, controls mainly the thermal structure of the stratosphere, despite its low abundance. Other compounds, such as phosphine (PH_3) are found only at a few ppm but also have pronounced effects on the spectrum of Saturn. Access to the composition of Saturn's atmosphere is limited by remote sensing to the outer layers, at pressures lower than 10 bar. The physical processes affecting the composition are of two origins: thermochemical reactions in the troposphere and photochemical reactions in the stratosphere.

Thermochemical reactions

Thermochemical reactions equilibrate to produce an average composition. A typical example is the conversion of carbon compounds between CH_4 and CO, through the reaction

$$CH_4 + H_2O \rightleftharpoons CO + 3H_2.$$

At temperatures lower than 2000 K, CH_4 is the dominant carbon-containing species, but, as temperature increases, the production of CO becomes more important. At the low temperatures of the atmospheres of the outer planets, thermodynamics would predict the presence of CH_4 only. Nevertheless, CO was observed in the atmosphere of Saturn, in 1985. One possible explanation for this observation is the presence of an out-of-equilibrium phenomenon, where kinetics of reaction is taken into account and not only the final equilibrium. The conversion of CO to CH_4 is inhibited at the low temperatures of the upper troposphere, because the above reaction is slow. If CO can be transported rapidly enough to atmospheric regions where the reaction rate becomes insignificant, it will remain unaffected, because of a too-slow kinetics. This mechanism, called quenching, transports a compound to a region of low reactivity, even if thermodynamic equilibrium seems to be violated. Indeed, on Saturn, the observed tropospheric composition is far from equilibrium. Disequilibrium species, such as PH_3, GeH_4 and AsH_3, have been observed on Saturn. PH_3 is particularly dominant, because of its strong bands in the infrared. These compounds are tracers of the composition of heavy elements compared with hydrogen and helium. For example, the phosphorus elemental ratio is found to be 5–10 times greater than on the Sun (according to submillimeter and infrared measurements), implying a composition of Saturn's atmosphere highly enriched in heavy elements. Similar enhancements seen for several compounds favor an inhomogeneous accretion scenario for the formation of Saturn, as discussed above.

Photochemical reactions

The stratosphere is accessible to UV photons, and photochemistry becomes a dominant process, with a completely different chemistry, compared with most of the troposphere. Each molecule is sensitive to a specific range of UV wavelengths, which penetrate to different depths, and the photochemical reactions start at different levels, for different molecules such as NH_3, PH_3 and CH_4. The photochemistry of CH_4 is found at the uppermost levels in the atmosphere, with the production of heavier hydrocarbons such as C_2H_6, C_2H_4 and C_2H_2 initially. These compounds, in turn, absorb the solar UV, dissociate, react with other molecules and form more complex products. Heavier hydrocarbons can ultimately condense in the stratosphere, and they are thought to be part of the stratospheric hazes. At deeper levels, NH_3 and PH_3 compounds are also photolyzed, with a production of N_2H_4 or P_2H_4; such compounds could also be an important source of haze particles.

A recent and unexpected discovery by the ISO satellite has given new insight into the complex processes of the photochemistry of the upper layers in Saturn's atmosphere. ISO observations have shown the presence of CO_2 and H_2O in the stratosphere. Oxygen compounds coming from the interior are efficiently trapped at the tropopause, as condensation of H_2O, the main reservoir of oxygen at Saturn, prevents water vapor from reaching the stratosphere in significant amounts. ISO observations suggest that there is an influx of external oxygen, coming probably from dust particles of the interplanetary medium, falling into the atmosphere of Saturn (as well as

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

into the other giant planets and Titan), or from the rings of Saturn. The presence of water and carbon dioxide strongly modifies the photochemistry, with different reactions with methane byproducts and the possibility of forming other constituents. From ISO observations, an average flux of 12 000 tons of material per day over Saturn has been estimated. The photochemical reactions between oxygen and carbon compounds can also become much richer than with pure methane in a hydrogen environment, with the possible production of many organic molecules, such as fomaldehyde (H_2CO).

Clouds

The giant planets exhibit many meteorological features and a large variety of cloud structures, apparent in telescopic observations (figure 2). The clouds appear when atmospheric gaseous compounds condense into liquids or solids at the cold temperatures found in the upper atmosphere (see CLOUDS IN PLANETARY ATMOSPHERES). As on the Earth, water clouds are expected in the troposphere, but the water clouds are hidden by upper cloud layers on Saturn. Above the water cloud, thermodynamic calculations predict the presence of two overlying layers, one cloud of ammonium hydrosulfide, NH_4SH, and another of ammonia ice, NH_3. The latter, an ammonia cirrus, is probably ubiquitous over Saturn's atmosphere, with an opacity varying with local meteorology. Individual clouds and spots seen in some images are probably the result of the lower less uniform cloud layers. The main difficulty in the interpretation of cloud structure is that the atmosphere is usually not in thermodynamic equilibrium, as we already know from the composition. To form a cloud, it is necessary not only to be at or below the condensation point but also to have nuclei of small particles to initiate the growth of cloud drops or crystals. A cloud is formed in a perpetual competition between small growing particles and large sedimenting particles.

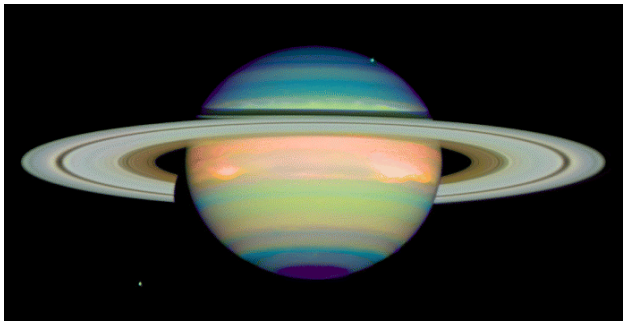

Figure 2. Saturn in false color from the NICMOS camera of the HST (STScI-PRC98-18). The false-color image shows indications of cloud layers. Green and yellow colors are sensitive to hazes above the cloud layers. Red and orange colors are sensitive to high clouds reaching the top of the atmosphere. Blue colors are an indication of a clear atmosphere down to the main cloud layer. Credit NASA.

The optical properties of the clouds largely depend on an extraordinarily complex microphysics, not always fully understood even in terrestrial water clouds. On Jupiter, the Galileo probe has shown that thermodynamically predicted clouds were probably present, but with different structure and altitude to what was thought before, because of local meteorological conditions. Above the main cloud layers, a haze of small particles is present on Saturn as well as on Jupiter.

Remote sensing observations of Jupiter and Saturn can measure with a reasonable accuracy the vertical distribution of small haze particles in the upper atmosphere, but the origin of the colors and morphology seen in the images remains mysterious. Minor constituents could possibly populate the clouds. These minor constituents (sulfur, phosphorus, etc) could be responsible for the coloration of Saturn's clouds. The structure of the clouds is also responsible for the different aspects of Saturn when seen at different wavelengths. Observations in a methane filter, where light is strongly absorbed by the atmosphere, are limited to the uppermost layers of the atmosphere. The regions of high clouds are therefore seen with better contrast. In the northern regions, an enhanced absorption is found in the UV. It is attributed to the presence of a polar haze. This haze could be formed by heavy hydrocarbons, generated by precipitating particles in the auroral regions, as on Jupiter, and condensing in the low temperatures of the lower stratosphere.

Photometric properties of clouds

The cloud structure has important effects on the radiative budget of Saturn. Variations in reflectivity govern the global absorption and reflection of the solar flux. Opacity variations also influence the reabsorption of the thermal flux inside the atmosphere, with pronounced consequences for the thermal structure.

To retrieve the atmospheric structure from photometric observations, one method is to measure center-to-limb variation: by measuring the variation of reflectivity along a parallel on Saturn's disk, vertical variations of the cloud structure are inferred. The scattering by small particles is observed at higher altitudes in the atmosphere close to the limb than at the central meridian, because of the more vertical path of the photons coming from the Sun at the center of the disk. The cloud structure of Saturn is found to be homogeneous in longitude, and variations occur mostly with latitude, as is apparent in the usual images in the visible, from ground-based or space missions (Voyager, HST).

Meteorology

As on Jupiter, the wind system on Saturn consists of a longitudinal banded structure, with strong westward winds at the equator, limited by eastward jets north and south. The

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

Saturnian cloud bands correspond roughly, although not exactly, to a system of easterly–westerly jets. The equatorial wind speeds are as high as 500 m s^{-1}, 4 times larger than on Jupiter, and directed in the sense of rotation. There is still no general agreement about the origin of these winds. On Jupiter, the Galileo probe measurements have shown that strong winds persist down to pressure levels of at least 20 bar, below the levels where solar energy has been deposited. It has been proposed that the internal heat source is the most likely source of these deep winds. The banded structure, on the other hand, is believed to be caused by convective motions in the form of columnar cells, chaotically built and destroyed permanently. Even though no completely realistic models of the dynamics of giant planets have been constructed yet, laboratory measurements on convection in rotating spherical shells show some similarities to the banded structure seen on the giant planets. At first glance, these experiments tend to support models explaining the wind structure by global convection in the whole planetary interior (or at least the upper part of the atmosphere above the metallic hydrogen transition). Another class of models explain the appearance of the giant planets by dynamical forcing by solar energy deposition. Even if solar energy is deposited at the external boundary, over long time scales the entire atmosphere can be moved as well. A competition between internal energy release and solar heating is probably at work, but the hydrodynamical problems pose a challenge to our current knowledge. Without a global model of atmospheric motions, the meteorology of Saturn remains mostly confined to a more phenomenological description of atmospheric structure.

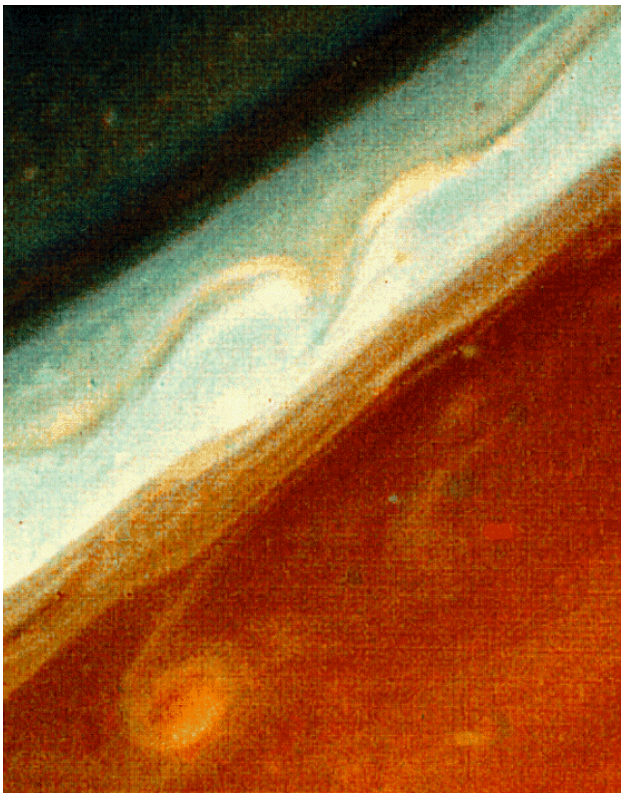

Figure 3. Spots on Saturn: image from Voyager 2 (Voyager 2, P-23919) in the northern temperate belt, showing an elongated atmospheric disturbance in Saturn's atmosphere on 20 August 1981. Credit NASA.

Spots

There is no feature on Saturn like the Great Red Spot on Jupiter, but several small ovals of various colors have been observed by Voyager (figure 3). At the time of Voyager observations, some symmetric, anticyclonic brown ovals (rotating clockwise in the northern hemisphere) were situated at 42°N, 5000 km × 3000 km in size. These spots have flows similar to the Jovian White Oval Spots. A unique structure present on Saturn during the Voyager epoch was a ribbon-like structure, located at 46°N, and described as a dark, wavy line moving at about 150 m s^{-1} eastward (figure 3). A so-called vortex street has also been observed. It represents a line of vortex with alternate direction of rotation, usually formed in turbulent flow in the wake of an obstacle. Generally, Saturn's atmosphere looks less active than Jupiter's. It must be noticed that the activity of the planet is observed through the cloud motions. Since clouds on Saturn are located deeper, owing to temperatures colder at corresponding pressure levels of Jupiter, they are more obscured by the overlying stratospheric hazes. Comparisons of the Jovian and Saturnian cloud activities should therefore be made cautiously.

Storms

One of the most striking differences in Saturn's meteorology compared with Jupiter is the periodic appearance of large storms on the former. Several events have been observed since 1876, showing an apparent periodicity related to the seasons of Saturn. Observations of such phenomena were made subsequently in 1903, 1933 and 1960. The last event was observed in 1990, and an image of Saturn soon after the beginning of the disturbance is shown in figure 4. The interpretation of these storms remains mysterious. They could correspond to a large convective cloud, originating deep in the atmosphere and redistributing a large amount of water to high altitudes. This cloud could therefore be compared to the equatorial plumes of Jupiter, which are also thought to correspond to water clouds, regularly spaced along the equator, and are present permanently. Another difference in the case of Saturn is the latitude of the storms, which varies from 5° to 58° (in 1960). If Saturn's storms are indeed convective water clouds, they would correspond to intermittent convection, with plume generation, as opposed to the more regular and permanent pattern of

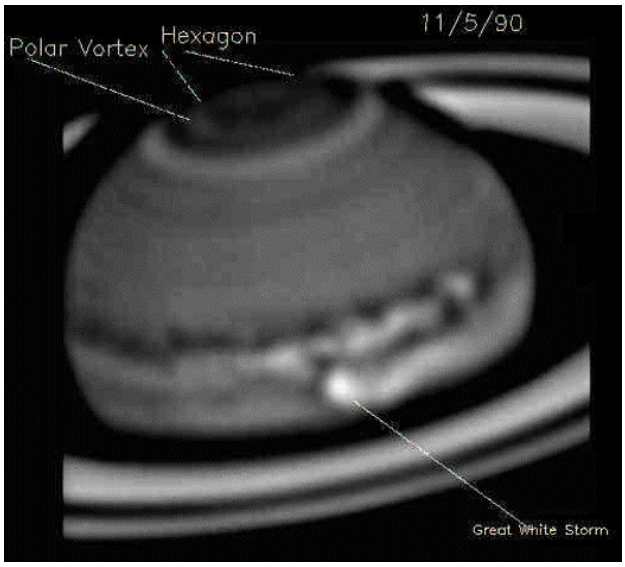

Figure 4. A giant storm on Saturn: image from Pic du Midi observatory, from October 1990, a few days after the emergence of a giant storm in equatorial regions. Several rare structures are seen in the northern regions also.

Jupiter. Such phenomena are indeed observed in the laboratory in experiments on convection. A difference in the thermal structure of Saturn, as compared with Jupiter, would result in differences in the convective activity. The observation of this storm was useful in completing the measurements of the wind field in the equatorial regions, which were obscured by the rings at time of the Voyager observations, but not in 1990 from ground-based observations.

Hot spots

One of the better-known features in Jupiter's atmosphere are the 5 μm hot spots. One of these is where the Galileo probe entered Jupiter's atmosphere. These spots are very bright in thermal emission at 5 μm. They represent regions of very low humidity, high transparency and low cloud coverage. On Saturn, there seem to be no features like Jupiter's hot spots. Water in the troposphere of Saturn has been measured from the ISO satellite, which found a very low water abundance. As for Jupiter, it has been attributed to some meteorological processes which decrease the water content of the atmosphere, as in Earth's deserts. The observation of an average low humidity despite the absence of hot spots seems therefore to argue for a different model of meteorology on Saturn than to that on Jupiter.

North polar regions

A special mention must be made about the north polar regions of Saturn. The Voyager 1 and 2 spacecraft recorded a strange hexagonal structure of clouds in the northern latitudes, and the presence of a particular spot, the North Polar Spot, named 'Big Bertha' by the Voyager imaging team. Since Voyager, this spot has been observed from the HST and from the ground, allowing planetary astronomers to follow its motion over a long period of time (figure 4).

Seasonal effects

Because of the 27° inclination of its axis, the north and south polar regions are alternatively in shadow during part of the orbital period of Saturn. Despite this long interval of 13 yr, no substantial effects are expected in the deep atmosphere, because the response time of the deep atmosphere to illumination conditions is much smaller than the orbital period, for pressures greater than several bars. The appearance of large storms seems to be periodic and could be related to Saturnian seasons, as mentioned above. Major seasonal effects are expected only in the stratosphere. The stratospheric thermal structure also depends on illumination effects and could exhibit seasonal variations. Indeed, the stratospheric temperatures measured by Voyager showed a difference in temperature at the 150 mbar level, the southern hemisphere being 6–8 K warmer than the northern, consistent with the modeling. Models of temperature variations predict a delay in the temperature response of the atmosphere subject to seasonal forcing, with maximum temperatures shifted by about one-sixth of a Saturnian year at 150 mbar. Finally, there is a possible influence of thermal effects on the underlying cloud structure, through the variation of the upper haze and the condensation of potential compounds of the stratospheric haze, such as N_2H_4 and P_2H_4, or the heavy hydrocarbons.

Aurorae

Although less intense than Jupiter's, Saturn's magnetic field also produces a large variety of magnetospheric effects. One of them affects the atmosphere. The observation of auroral emissions (see AURORA) in an atmosphere corresponds to the precipitation of charged particles from the magnetosphere, guided along the magnetic field lines and falling into the atmosphere. Saturn's strong magnetic field is, as for Jupiter, associated with auroral effects, mainly represented by the emissions of hydrogen molecules and ionospheric byproducts, in particular H_3^+. The emissions of hydrogen molecules and atoms can be seen only from space, as in figure 5 observed from the HST. These emissions are located along ovals, whose pattern is directly related to the geometry of the magnetic field. As on Jupiter, a complete oval is observed in the H_2 bands. Auroral emissions on Saturn have also been observed from the ground in the infrared through the emission of a molecular ion present in the ionosphere, H_3^+. The aurorae on Saturn correspond to a total deposition of energy estimated to be 10^{11} W, about 100–1000 times fainter than on Jupiter. Unlike Jupiter, where the internal

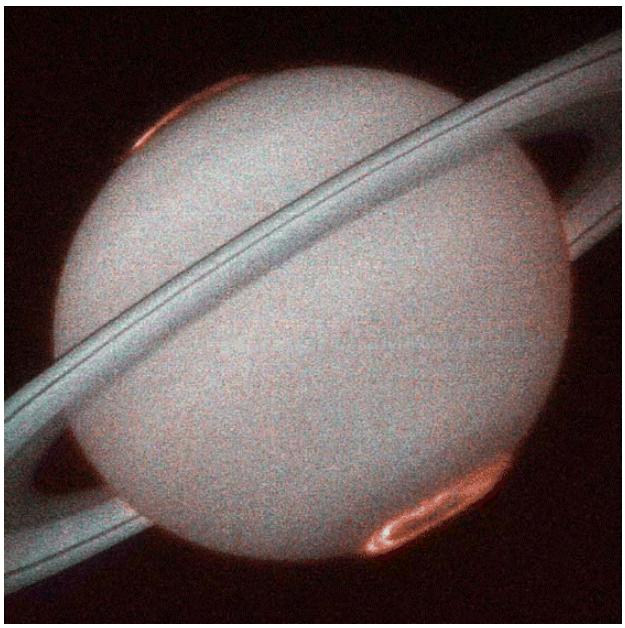

Figure 5. HST aurorae on Saturn (STScI-PRC98-05). Image of ultraviolet aurora, taken from the HST Imaging Spectrograph in October 1997. Credit NASA.

magnetosphere is populated by particles produced by the Galilean satellites, Saturn's aurorae are more dependent on the SOLAR WIND, which is 4 times fainter at Saturn because of the distance to the Sun. Saturn appears therefore as an intermediate case between Jupiter and the Earth for auroral processes.

Future observations

The Cassini spacecraft will enter the Saturnian system in 2004 and will provide extensive observations of Saturn, its moons (see SATURN: SATELLITES) and its rings. Although Titan is considered as the main objective of the Cassini–Huygens mission, the atmosphere of Saturn will also be extensively observed by remote sensing instruments during the mission. Several objectives are expected to be satisfied from this mission from the close study of composition variations and of the dynamics of the system. Unprecedented spatial resolution will be obtained on the cloud features, the cloud structure will be observed at angles inaccessible from the Earth and the night side of Saturn will reveal the thermal emission without contamination by the solar reflection which affects ground-based measurements. Many of the open questions mentioned above should find a solution after the Cassini observations, and many others will probably arise.

Web update

The discovery of twelve new moons of Saturn brings the planet's total to 30: the most in the Solar System. The new moons vary between about 6 and 30 km in diameter, and are moving in irregular, tilted orbits. They fall into several clusters, leading Brett Gladman, of the Observatoire de la Cote d'Azur, Nice, France, and colleagues to conclude that they are the remnants of larger satellites that have been fragmented by collisions. The moons probably began life as wandering bodies that were captured by Saturn's gravity. Gladman and colleagues found the moons by scanning Saturn with sophisticated electronic detectors mounted on medium-sized, ground-based telescopes.

Saturn Nebula (NGC 7009)

A planetary nebula in the constellation Aquarius, position RA $21^{h}\ 04.4^{m}$, dec. $-11^{\circ}\ 22'$. It measures $25''$ and shines with a greenish hue. It is of eighth magnitude and for a planetary nebula has a high surface brightness. Two small lobes on either side give it the appearance of the planet Saturn.

Saturn: Magnetosphere

Perhaps the most awe-inspiring sight in our solar system, which can be appreciated by even a modest telescope, is that of the planet SATURN, with its banded atmosphere and delicate ring system. Saturn is the sixth planet away from the Sun at a distance of 9.5 AU. Saturn is the second-largest planet in our solar system after JUPITER with a radius of 60 330 km (defined as $1R_S$), and has a rapid rotation rate of 10 h and 39.4 min. This rapid rotation rate generates a centrifugal force that causes the equatorial regions of the planet to bulge outwards and the poles to flatten. Saturn is the least dense of all the planets and does not have a solid surface. Instead the planet consists of an enormous sphere of gas that gradually compresses to liquid deep beneath the clouds.

The rings of Saturn were first observed by Galileo in 1610, although because of the poor quality of his telescope he did not recognize them as such. He initially declared that Saturn consisted of three different planets, and then later he observed Saturn as first a single planet and then one that seemed to have developed side handles. It was only in 1655 that Huygens, with a telescope of far better quality, was able to propose that Saturn actually had rings in orbit around the planet. These rings we know today consist of countless individual particles that range from a fraction of a centimeter in radius to a few meters, with each particle having its own orbit around the planet.

The current count of satellites which orbit around Saturn is 18 and the biggest of these is Titan, which is unique in the solar system since it is the only moon to have its own atmosphere. Saturn has had three spacecraft fly past it, Pioneer 11 and Voyagers 1 and 2, the last taking place in 1981. The Cassini mission, which will spend 4 yr orbiting around Saturn, was successfully launched on 15 October 1997 and will reach Saturn in July 2004.

The magnetosphere is the volume around the planet that is dominated by Saturn's magnetic field. The magnetosphere of Saturn results from the interaction of the solar wind with the magnetic field of the planet, with the solar wind being deflected around the planet by the pressure of the planetary magnetic field.

This cavity is compressed on the Sunward side of the planet, under the influence of the pressure of the solar wind, and is drawn out into a long magnetotail on the nightside of the planet. Magnetospheric cavities form around any magnetized planet, for example, at the Earth and Jupiter (see MAGNETOSPHERE OF EARTH; JUPITER: MAGNETOSPHERE). Figure 1 shows a schematic of the Saturnian magnetosphere with the solar wind impinging onto the planetary magnetic field from the left. The shock wave that results, the bow shock, is shown by the dotted curve, and this results in the solar wind slowing down as well as being heated and deflected around the planet. The broken curve, the magnetopause, separates the flowing solar wind from Saturn's magnetic field. Saturn, like the Earth, has the magnetopause and bow shock at a standoff distance from the planet that scales with solar wind dynamic pressure. The region between the bow shock and magnetopause is known as the magnetosheath. The cusp region, as shown, allows magnetosheath particles entry into the magnetosphere since that is where the magnetic field is weakest. Full curves show the magnetic field lines of the planet. The cavity which forms the magnetosphere is filled with electrons, protons, ions, molecules, energetic particles and charged dust grains, with the charged particles and dust grains interacting with the electric and magnetic fields which are present. The charged particle motion generates currents within the magnetospheric plasma; the main current systems that exist are those due to the magnetopause, the equatorial ring current and a cross-tail current in the magnetotail.

The nightside of the planet shows a fully developed magnetotail that has been observed to be about $40R_S$ in diameter at $25R_S$ downtail. This magnetotail develops as a result of the solar wind flow past the magnetopause that aids in pulling the planetary field lines in an anti-Sunward direction. This magnetotail which may extend hundreds of R_S downstream acts as a reservoir for energy and plasma. Shown in figure 1 are magnetic reconnection processes which generate plasma bubbles or plasmoids. It has been postulated that these break off from the Saturn magnetotail and escape downtail just as occurs at the Earth. The outer magnetosphere (close to the magnetopause) and magnetotail are thought to be the primary regions where energy from the solar wind is transferred to the magnetospheric plasma.

TITAN, the largest moon of Saturn, orbits the planet at a radial distance of $20R_S$. Depending on solar wind conditions, Titan can be found in the magnetosphere (as shown in the figure), or in the magnetosheath or out in the solar wind (see SATURN: MAGNETOSPHERE INTERACTION WITH TITAN). During the previous planetary flybys of Saturn, a variety of solar wind conditions generated varying sizes of magnetospheric cavities, and this will be discussed later.

The magnetosphere

The magnetosphere is defined as being everywhere inside of the magnetopause, and comprises the magnetic and electric fields, plasma, energetic particles, the rings and some of the satellites.

Saturn's magnetic field

The behavior of the magnetosphere of Saturn is controlled by the magnetic field of the planet and hence in order to understand magnetospheric dynamics we need to understand the planetary magnetic field. The intrinsic magnetic field of Saturn was first measured by the PIONEER 11 spacecraft which flew past the planet in 1979. This spacecraft observed not only the intrinsic magnetic field but also the accompanying magnetosphere. The equatorial ring current was implied by the Pioneer 11 observations, and its existence was confirmed by the VOYAGER 1 and 2 flybys in 1980 and 1981.

The equatorial ring current is of the order of 10^7 A and flows eastward around the planet between radial distances

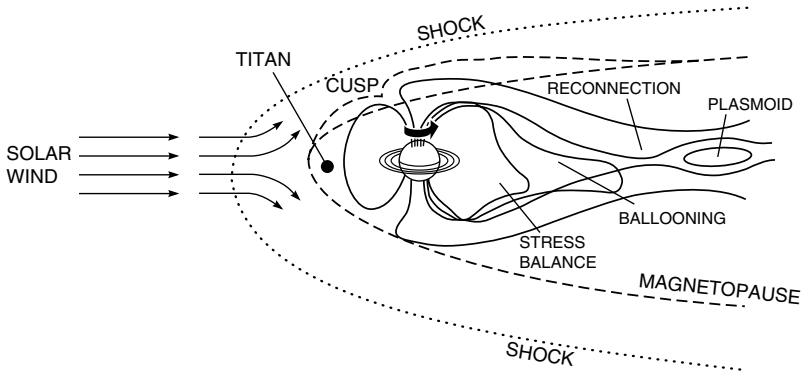

Figure 1. The magnetosphere of Saturn, with the solar wind flowing in from the left. The bow shock and magnetopause are shown, as are various processes within the magnetosphere. Titan is shown just inside the magnetopause. The large full arrow denotes the rotation direction of Saturn.

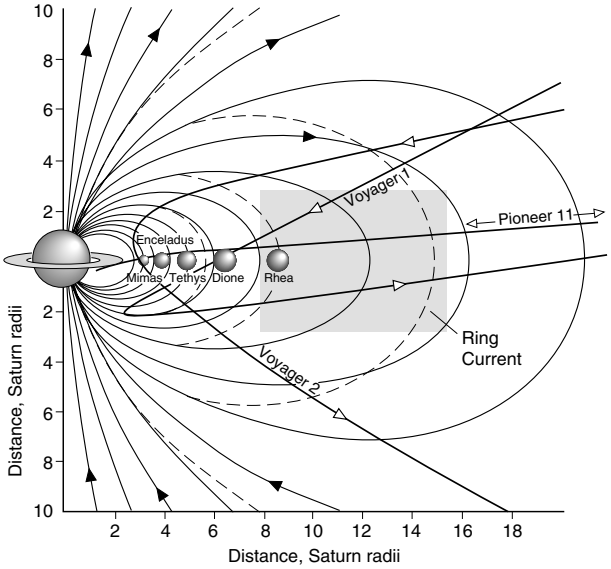

Figure 2. A meridian plane projection view of the magnetic field of Saturn (in a planet-centered cylindrical coordinate system). The broken curves represent dipole field lines and the full curves represent field lines that have been distended radially outwards as a result of the influence of the equatorial ring current. The shaded region shows the position of the ring current plasma. The flyby trajectories of the Pioneer 11 and Voyager 1 and 2 spacecraft are also shown. (Based on and courtesy of Connerney *et al* (1983) and Spilker (1997)). Figure 4 reveals a view of the flyby trajectories with respect to local time.

of $8R_S$ and $16R_S$. This ring current is generated by the drift of ions and electrons in opposite directions around the planet. Current flow in a plasma generates magnetic fields, and the ring current results in the dipole-like magnetic field lines of the planetary field being stretched outwards in a radial direction (although this radial distension is moderate when compared with the field lines at Jupiter). Figure 2 shows a view of the magnetic field at Saturn, with the broken curves denoting dipole field lines and the full curves containing not only the dipole field but also the contribution from the ring current as well. The shaded area shows the ring current and the dark full arrows show the direction of the magnetic field, with the open arrows revealing the direction of motion of the three spacecraft which have already visited Saturn.

On the nightside of the planet a well-developed magnetic tail occurs such as is found at the Earth and Jupiter. Effects of currents in the magnetotail as well as on the magnetopause need to be taken account of as far as their contribution to the magnetic field observed at Saturn is concerned. The planetary field as has been observed so far is primarily that of a dipole with a magnetic moment of $0.21R_S^3$ G. The polarity of the magnetic field is opposite to that of the Earth, that is positive from north to south, and therefore is in the same direction as that of Jupiter. The magnetometer observations from the Pioneer 11 and Voyager 1 and 2 spacecraft revealed quadrupole and octupole terms as well, although no non-axisymmetric terms could be resolved from the observations. Hence the magnetic field shows a remarkable symmetry about the rotation axis of the planet with there being a less than 1° tilt between the dipole and rotational axes. This is a unique feature in our solar system with all other magnetized planets having significant tilts between the dipole and rotational axes, for example the Earth has an 11.5° tilt and Jupiter has one of 9.6°. If, however, the internal field at Saturn has, like those of the other giant planets, been formed by dynamo action deep inside the interior of the planet, then one would expect non-axisymmetric coefficients to be present in the field (that is, an asymmetry in longitude around the planet). The circulation of conducting fluids deep in the planetary interior generates dynamo action, where the two physical processes of convection and planetary rotation in turn generate the interior magnetic field.

Not only does dynamo theory imply the existence of a non-axisymmetric magnetic field but there are also other observations that seem to confirm this: for example, rotational modulation of kilometric radiation near local

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

noon in the northern hemisphere, a periodic variation which occurs in optical spoke activity in one of the rings and auroral brightening at the poles at specific longitudes. All of these observations seem to imply that longitudinal asymmetries do in fact exist in the magnetic field close in to the planet although they have not yet been observed by spacecraft magnetometers. The most likely reason why such non-axisymmetric terms have not been observed is that they are very weak in comparison with the stronger axial terms, and the magnetometer onboard Cassini has been designed and built specifically with such measurements in mind.

Plasma

The behavior of the plasma in Saturn's magnetosphere can be separated into three distinct regions as are shown in figure 3. The left-hand side of the figure shows the magnetosphere at noon local time whereas the right-hand side reveals the behavior in the dawn magnetosphere. The inner plasma torus is characterized by the presence of dense low-energy ions and electrons at low temperatures (<10 eV, where an eV is equivalent to 11 605 K) and high densities of about 100 cm^{-3}. The inner region of the plasma torus, inside of $4R_S$ is thin, of the order of $0.4R_S$. Between $4R_S < r < 8R_S$, the plasma sheet thickens out to about $2R_S$ with a density of a few cm^{-3} and is oxygen rich owing to sputtering from the satellites Dione and Tethys. This outer region of the torus extends to just beyond Rhea's orbit.

In between the inner torus and the hot outer magnetosphere is an extended equatorial plasma sheet with enhanced levels of cold plasma. This is probably the primary contributor to the equatorial ring current. This plasma sheet extends out to about $15R_S$ and has a thickness of $8R_S$, density between 0.1 and 2 cm^{-3} and an electron temperature of 10–100 eV. The inner edge of the extended plasma sheet coincides with a vast cloud of neutral hydrogen that extends beyond $25R_S$, shown by the dot-filled circle. This neutral hydrogen probably escaped from Titan and the other satellites. At the inner edge there are very hot ions of the order of thousands of eV which are most probably new-born ions that have been heated by planetary rotation.

Beyond the extended plasma sheet lies the hot outer magnetosphere which consists of a highly variable region that coincides with the Titan-produced hydrogen–nitrogen torus. This torus maintains the density between about 0.01 and 0.1 cm^{-3} and the temperature between 50 and 800 eV (about 10^6 K). Near noon local time, cold density enhancements were observed by the Voyager 1 and 2 spacecraft which also correspond to drop-outs in the magnetic field. The Voyager 1 enhancements have been described as the spacecraft having crossed through plumes of Titan. Titan is a direct source of plasma, with the plasma streaming away from Titan in the local corotation direction and thereby generating a plume of plasma. These plumes tend to remain in the equatorial plane and will slowly over time merge with the background plasma. For the Voyager 2 flyby, Titan was not inside the magnetosphere, but was rather in the magnetosheath plasma and nowhere near the spacecraft itself. The cold density enhancements and magnetic field drop-outs which were observed have been described as plasma bubbles which have broken away from the edge of the extended plasma sheet. Similar types of plasma bubbles have also been observed at Jupiter and may be symptomatic of plasma transport processes in fast-rotating magnetospheres.

In all three regions of the magnetosphere the plasma particles tend to be concentrated in a disk in the equatorial plane where most of the plasma sources are located. Titan acts as a significant source of plasma in the Saturnian magnetosphere, as does the vast hydrogen torus, with the other satellites playing a role as well, the importance of which is yet unclear.

Energetic particles

Saturn like other planets in our solar system has populations of energetic particles, which are trapped by the planetary magnetic field. These trapped energetic particles, similar to the Van Allen radiation belts at the Earth, interact with the inner satellites and rings of Saturn. In the inner magnetosphere, inside of about $10R_S$, the ions tend to rigidly corotate with the planet, with the planet enforcing this through the magnetic field. The potential sources for these energetic particles are the solar wind, cosmic rays, ionized gas from the ionosphere of the planet and gas from the rings and satellites. The energization of these particles remains unclear and is one of the many questions that scientists with instruments onboard the Cassini spacecraft hope to answer.

The motion of charged particles in a magnetic field is described by adiabatic theory, and there are three distinct motions that take place. The particle gyrates around the field line as well as moving along it. There is also a slow drift of the energetic particles through the magnetic field, with the ions drifting one way and the electrons the other. The radiation belts are made up of the energetic particles moving in helical orbits along the magnetic field lines, with the particles being reflected or mirrored near the poles and therefore bouncing back and forth on the field lines.

The energetic particles in the inner magnetosphere are severely affected by the rings and inner satellites in a number of different ways. The energetic particles can be swept up by collisions with the satellites, the rings and satellites can act as sources of secondary particles as well as sources of gas and dust. The core of the radiation belts is made up of high-energy protons, above 1500 eV, inside of the orbits of Enceladus and Mimas. In the outer regions of the magnetosphere there is a population of low-energy electrons of tens of eV and at the magnetopause there is a large increase in the proton and electron population below 500 keV.

Rings

The rings of Saturn remain one of the great mysteries of our solar system and the more we find out about them the more questions seem to arise (see SATURN: RINGS).

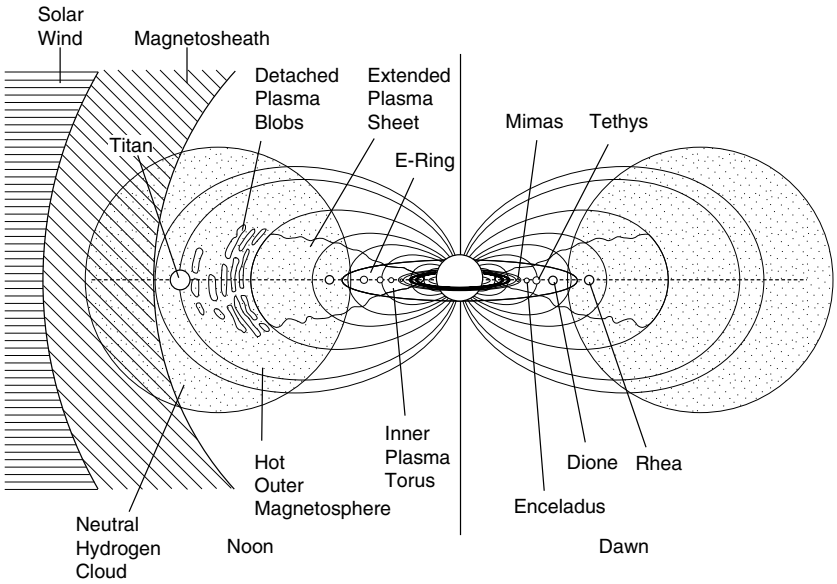

Figure 3. The different plasma regions of Saturn's magnetosphere, where the noon meridian is shown on the left of the figure and the dawn meridian on the right. The inner plasma torus, extended plasma sheet and hot outer magnetosphere are all shown with respect to the position of the rings and some of the inner satellites. The neutral hydrogen cloud is shown by the dotted circles, the magnetosheath as angled straight lines and the solar wind as straight lines. (Based on and courtesy of Sittler *et al* (1983)).

With Earth-based optical telescopes, one is able to differentiate distinct zones to the rings and with spacecraft flybys and Earth-orbiting telescopes further ring divisions have been observed. The outer zone, known as the A ring, is separated from a bright inner zone, the B ring, by a gap known as the Cassini division. Inside of the A and B rings is a semitransparent ring, the C or crepe ring. There are also a large number of smaller rings labeled through from the D through to the G ring, which were named in order of discovery and not in order of placement from the planet. The A and B rings are known to be composed of nearly pure water ice and dark, nearly radial lines or spokes have been observed in the B ring. There seems to be a link between the formation of these dark radial wedge-shaped features that appear on the ring and the rotational period of the magnetic field and Saturn kilometric radiation (SKR), and hence there must be an interaction between the electromagnetic fields of Saturn and the ring system.

Waves have been observed to propagate through the rings. The rings are made up of particles ranging in size from a few millimeters to several meters. These particles are bright and backscatter light rather strongly, behaving in a similar fashion to rough icy blocks. Moonlets have been observed within the ring system by the Voyager spacecraft, some of which seem to act as shepherds to the smaller rings. Some of the ring regions contain fine dust particles, which implies a link between the ring system and the magnetosphere of Saturn.

Even though we have been able to learn a great deal about this fascinating ring system there still remain a great deal of unanswered questions, some of which will be answered by the Cassini mission.

The icy satellites

There are at least 18 satellites orbiting about Saturn and there may well be other small yet undiscovered satellites as well (see SATURN: SATELLITES). All of these satellites are cratered to some extent and range from the biggest planet-like Titan with its own dense atmosphere to tiny irregular objects just tens of kilometers in diameter. The positions of some of the larger satellites are shown in figures 2 and 3. Mimas, which is at a distance of $3.08R_S$ from Saturn with a radius of 197 km, is heavily cratered and there is very little evidence for thermal evolution or resurfacing having taken place. Enceladus, at $3.95R_S$ from the planet, has a radius of 251 km and is a good reflector. It shows no large craters but there is some indication of large-scale surface changes having taken place which therefore implies some type of internal activity having taken place. Its orbit coincides with the densest part of the E ring and one of the questions which needs to be answered by Cassini is whether Enceladus could be the source of particles for the E ring.

Tethys, at $4.9R_S$ from Saturn with a radius of 530 km, also reflects well and is very densely cratered. Dione out at $6.3R_S$ from the planet has a radius of 560 km and a bright icy surface and there is evidence of past internal activity with numerous craters and valleys and troughs on the surface. Rhea is the outermost and largest of the inner icy satellites at $8.3R_S$ with a radius of 765 km and has well-formed craters on the surface. Before discussing Titan in some detail, Iapetus out at $59R_S$ from Saturn with a radius

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

of 730 km deserves a mention. Iapetus has a great many craters on its surface and a density similar to the other icy satellites, which is consistent with water ice being the major constituent.

Titan

Titan, at $20R_S$ from Saturn and with a radius of 2575 km, is the second largest satellite in the solar system after Jupiter's moon Ganymede. It is unique in the sense that it is the only satellite in our solar system with its own atmosphere, which is dense and predominantly consists of nitrogen and methane. Until very recently the surface of Titan has remained hidden beneath an orange hydrocarbon haze, which is formed as a result of methane in the atmosphere being destroyed by sunlight. Recent images from the Hubble Space Telescope (HST), however, in near-infrared wavelengths (to which the haze is transparent) have revealed a surface feature on Titan of about 4000 km across (about the size of Australia).

An interesting issue for Titan concerns the relationship of the atmosphere, its surface and its interior. Its atmosphere is believed to be filled with complex organic molecules similar to the atmosphere of primordial Earth. Titan is the sole focus of the Huygens probe as well as a main target of the Cassini orbiter.

The Galileo orbits of Jupiter (see JUPITER: SATELLITES) have revealed that both Ganymede and Io have internal magnetic fields of their own. Titan has a size and density very similar to Ganymede and this raises the possibility that Titan and possibly some of the other Saturnian satellites may have internal fields of their own, either intrinsic like Ganymede's or remnant such as has been recently observed at Mars. The study of any induced or intrinsic fields associated with satellites is important for a variety of reasons. It allows a better understanding of the interior structure, composition and dynamics of the satellites, the way in which particles from the magnetosphere impinge on the satellite and how this affects the evolution and generation of magnetic fields in solid bodies in the solar system.

Saturn as a radio and wave source

For 20 yr before the Voyager missions reached Saturn, scientists had been searching for radio emissions at Saturn. There were no radio astronomy investigations onboard the Pioneer 11 spacecraft and it was only when Voyager 1 was within 3 AU of Saturn that radio emissions were first measured, thereby confirming Saturn as a radio source, although a much weaker source than Jupiter.

There are three distinct components to the radio spectrum, kilometric radiation, which we will discuss in some detail, together with narrowband noise and related continuum and electrostatic discharges. SKR appears from the auroral regions in both the northern and southern hemispheres. There are localized regions near noon local time that are evident with the most fundamental period observed occurring at the rotation period. This is one of the observations which tends to disprove the validity of the very symmetrical magnetic field which has been measured to date. The source energy of the SKR seems to be the solar wind, with a strong correlation being in evidence between the solar wind and SKR including a 25 day periodicity (which is the solar rotation period).

In a magnetized plasma such as a planetary magnetosphere, a whole range of different types of waves are produced which are trapped inside the magnetosphere. These radio and plasma wave emissions range from a single frequency (narrowband) through bursty and broadband (several frequencies) to continuous frequencies. The types of waves range from electromagnetic, sound and gravity waves (such as are supported in gases and fluids), to an entire range of waves unique to a magnetized plasma, such as Alfvén waves, magnetosonic waves and ion and electron cyclotron waves for example. The variety of waves trapped inside of Saturn's magnetosphere will be measured by the Cassini instruments.

Auroral processes

Saturn, like the Earth and Jupiter, has aurorae generated at its north and south poles. These aurorae are caused by charged particles depositing their energy in the upper atmosphere. The auroral emission is generated when the energetic particles interact with gas in the atmosphere; in the case of Saturn this gas is molecular and atomic hydrogen.

The Voyager spacecraft first detected the Saturn aurorae. Recent HST images of the aurorae have revealed both light and dark aurorae at the planet. The light aurorae have been observed at other magnetized planets but the dark auroral oval which was observed encircling the north magnetic pole is unique in the solar system. This seems to represent an excess of absorption of sunlight by the atmospheric particles that are a product of the auroral process.

Magnetospheric processes

Figure 4 shows a view of the Saturnian magnetosphere in the equatorial plane, with the Sun to the left of the figure, the nominal bow shock denoted by the full curve marked $\overline{S}$ and the nominal magnetopause again shown as a full curve and denoted by $\overline{MP}$. The magnetosphere is not usually static, however (as it is being shown in this figure), and for the three planetary flybys that are shown as broken curves a variety of solar wind conditions existed.

During the Pioneer 11 flyby in 1979, a fast solar wind stream inbound caused a bow shock to form upstream at $17.3R_S$ away from the planet. On the outbound pass during which time the solar wind must have been rather variable there were numerous magnetopause and bow shock crossings. Voyager 1 in 1980 observed a magnetosphere during relatively stable solar wind conditions with single bow shock crossings both inbound and outbound. The Voyager 2 flyby in 1981 occurred during extremely disturbed solar wind conditions, with initially an interplanetary shock wave being measured 3.5 days before the first bow shock encounter. An

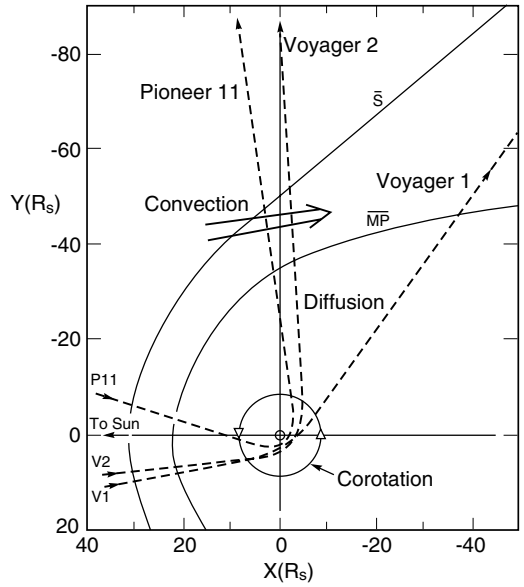

Figure 4. A view of the Saturnian magnetosphere in the equatorial plane, in a coordinate system which is Saturn centered with X positive in the direction from the planet to the Sun, Z positive along the rotation axis and Y completing the right-handed set. The nominal bow shock ($\bar{S}$) and magnetopause ($\overline{MP}$) positions are shown. The inbound and outbound trajectories of the Pioneer 11 and Voyager 1 and 2 spacecraft are shown by the broken curves, with the arrows showing direction of motion. The various regions of plasma circulation, that is corotation, diffusion and convection effects, are also shown. (Based on and courtesy of Sittler *et al* (1983)).

interplanetary current sheet was then observed some 12 h later, all of which resulted in five different bow shock crossings inbound (between $31.5R_S$ and $23.6R_S$). The magnetopause was observed at $18.5R_S$ inbound and then an expansion of the magnetosphere occurred with numerous magnetopause and bow shock crossings on the outbound pass; the final magnetopause crossing occurred at $70.4R_S$. Another explanation for this extremely disturbed behavior could be that Saturn in fact passed through an extended Jovian magnetotail during this flyby.

In planetary magnetospheres there are two main sources of energy which drive the physical processes which take place, those of the solar wind and the planetary rotation. This in turn results in two main types of large-scale plasma flow, those of convection and corotation. Convection describes the flow of plasma in a tailward direction, which results from the solar wind dragging magnetic field lines past the planet (as shown in figure 4). The term convection was first used for this process in the Earth's magnetosphere, where it was noticed that plasma flowed over the poles of the planet from noon towards midnight and then back again towards the dayside at lower latitudes. The type of flow pattern that results was very similar to flow cells that are thermally driven and hence the term convection has been used ever since. The fast rotation of Saturn and its magnetic field causes a large-scale electric field to form, which extends out into the magnetosphere. This in turn causes the magnetospheric plasma to rotate with the planet and the magnetic field, that is the plasma corotates with the planet. Now, at the Earth, solar wind processes dominate the magnetosphere, with the convection pattern usually penetrating halfway from the magnetopause to the Earth. At Jupiter, its very fast rotation rate ensures that the circulation of magnetospheric plasma is dominated by the planetary rotation. The Saturnian magnetosphere is somewhere in between the two cases, with both convection and corotation playing an important role. Corotation effects seem to dominate close to the planet, inside of Rhea's orbit out to about $9R_S$, as revealed in the figure. Convection processes seem to dominate much further out close to the bow shock and magnetopause, with the plasma in the outer magnetosphere being moved by large-scale convection. One of the goals of the Cassini mission is to better understand the role of these two plasma circulatory processes at Saturn. In addition to these rapid transport processes there is also the more uniform redistribution of plasma which occurs by means of diffusion within the magnetosphere itself.

The Cassini–Huygens mission

Cassini–Huygens is a joint NASA–ESA mission, which was successfully launched from Cape Canaveral, Florida, on 15 October 1997. Its aim is to study the Saturn–Titan system, with the Cassini orbiter orbiting Saturn for 4 yr beginning in July 2004 and the Huygens probe which will descend through the atmosphere of Titan in November 2004. This mission is named after two astronomers who pioneered observations of Saturn. The orbiter is named after Jean-Dominique Cassini who discovered the moons Iapetus, Rhea, Dione and Tethys, as well as ring features such as the Cassini division, during the period 1671–1684, and the probe is named after Christiaan Huygens who discovered Titan in 1655.

The general science targets for Cassini–Huygens can be divided into five main categories: that of Saturn itself, the rings, the icy satellites, Titan and the magnetosphere of Saturn. Although Titan is primarily the target of the Huygens probe, which will descend through the atmosphere onto its surface, it will also be studied by the Cassini orbiter during 40 or so flybys of the moon.

The Cassini–Huygens mission is described in detail in the article on the CASSINI MISSION as are the science objectives of the mission. This section will simply give a brief description of the magnetospheric objectives of the mission.

The science objectives for the magnetosphere of Saturn are to determine the configuration of the nearly axially symmetric magnetic field and its relationship to SKR. Current systems, the composition and sources and sinks of the charged particles within the magnetosphere will also be determined. Wave–particle interactions that take place within the magnetosphere will be investigated,

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

as will the dynamics of the dayside magnetosphere and the magnetotail. The interaction of the magnetosphere with the solar wind, satellites and rings will also be studied.

A comparison will be made between the solar wind interaction that occurs at Saturn and those that occur at the Earth and Jupiter. At Earth, the magnetosphere is dominated by the solar wind whereas at Jupiter the magnetosphere is dominated by the rapid rotation rate and the internal plasma sources. Saturn's magnetosphere is likely to be somewhere in between these two extremes. It is more likely to mimic that of Jupiter since it too has a fast rotation rate and internal plasma sources, Titan and the icy satellites. Understanding the plasma dynamics at Saturn will allow a better understanding of the dynamics of planetary magnetospheres in general.

Saturn: Magnetosphere Interaction with Titan

Titan is the largest satellite of SATURN with an orbital distance from that planet of 20.6 Saturn radii (R_S), at which distance it will usually finds itself within Saturn's outer magnetosphere, where it interacts with the magnetospheric plasma. Titan is, after Jupiter's satellite Ganymede, the second largest satellite in our solar system and it possesses both an atmosphere and an ionosphere, which together act as an obstacle to the flow of Saturn's magnetospheric plasma that is incident on that satellite.

Introduction

Titan apparently does not have a significant intrinsic magnetic field. Consequently, the external plasma flowing nearby impinges directly on Titan's upper atmosphere and ionosphere. In contrast, at the Earth the solar wind plasma is deflected by Earth's strong intrinsic magnetic field. Titan is usually located inside Saturn's magnetosphere and the external plasma is the magnetospheric plasma, but occasionally solar wind conditions are such that Titan lies outside Saturn's magnetopause so that the external plasma encountering Titan is the solar wind.

Most of what we know about Titan and its interaction with Saturn's magnetosphere derives from data gathered by the VOYAGER 1 spacecraft when it encountered Titan on 12 November 1980. Titan was located within the Saturnian magnetosphere on this occasion. The radial distance of Voyager's closest approach to Titan's center was 6900 km, and the trajectory was downstream of the satellite with respect to the motion of the magnetospheric plasma. Titan's radius is 2575 km (R_T); hence, the radial distance of closest approach was $r = 2.67 R_T$. General information on Titan can be found in the main article TITAN.

The plasma instruments on Voyager 1 observed clear signatures of a plasma wake, in which the plasma densities were much greater than, and the temperatures much lower than, those in the ambient, external, magnetospheric plasma. The plasma wake is located downstream of Titan with respect to the external magnetospheric flow. The magnetometer on Voyager 1 observed a magnetotail coincident with the plasma wake. In this magnetotail, the measured magnetic field pattern was characteristic of field lines 'draped' around an obstacle (figure 1). Plasma wakes and magnetotails are also present at most planets and solar system bodies, and for objects such as Venus, Mars and comets, which lack significant intrinsic magnetic fields yet possess significant atmospheres. The tails are formed by a draped external magnetic field. Titan provides another example of the interaction of an externally flowing plasma with a non-magnetic body which has a significant atmosphere. A schematic diagram of the Titan interaction is shown in figure 2. In the rest of this article, a brief description of the atmosphere will be followed by a description of the ionosphere, and then the magnetospheric plasma interaction with the atmosphere and ionosphere will be revisited in more detail.

Titan's upper atmosphere

The atmospheric surface pressure of Titan is 1.45 bar and the surface temperature is a chilly 94 K. The dominant atmospheric species is molecular nitrogen (N_2), but there is a considerable abundance of methane (CH_4) with a mixing ratio in the range 2–10% in the lower atmosphere. Many other species are present at lower abundances, including ethane (C_2H_6), propane (C_3H_8), acetylene (C_2H_2) and hydrogen cyanide (HCN). In the upper atmosphere, molecular nitrogen is the most abundant neutral below an altitude of about 1700 km, but methane becomes the dominant neutral constituent above this altitude. At very high altitudes ($z > 2500$ km), molecular hydrogen (H_2) and atomic species such as N and H become more important.

A planetary exosphere is the uppermost region of a neutral atmosphere, in which the collision mean free path exceeds the scale size (or scale height) of the atmosphere (see also PLANETARY ATMOSPHERES). The exobase is the lower boundary of the exosphere, and for Titan the exobase is located at a radial distance of about $r \approx 4200$ km (or an altitude of $z \approx 1500$ km). In figure 2, the exosphere starts midway through the region labeled ionosphere. A considerable escape flux of H and N, and other species, is produced in Titan's exosphere due to the dissociation of CH_4 and N_2. The exosphere and ionosphere act as sources of ionized and neutral material for the outer magnetosphere of Saturn. The extended neutral exosphere of Titan strongly affects the interaction of Titan with the magnetosphere, giving this interaction a 'comet-like' character.

Titan's ionosphere

An ionosphere is an atmospheric region, or layer, consisting of charged particles (electrons and ions). Ionospheres form around any planet which possesses an atmosphere and are produced by the ionization of neutral atoms and molecules (see also PLANETARY IONOSPHERES). The ionosphere coexists with the neutral upper atmosphere. The main ionization sources in any planetary ionosphere, including the Earth's, are photoionization of neutrals by extreme ultraviolet (EUV) solar photons and electron-impact ionization of neutrals by fast electrons. The energy of the ionizing photon or ionizing electron must exceed the ionization potential of the relevant neutral (this energy is typically in the range 10–20 eV). The electrons are either photoelectrons produced by photoionization or energetic electrons which have traveled from the adjacent planetary magnetosphere. For example, the auroral displays observed at high latitudes on the Earth are produced by collisions of energetic electrons with oxygen and nitrogen atoms and molecules in the upper atmosphere. These electrons originate in the magnetotail region of EARTH'S MAGNETOSPHERE and follow magnetic field lines that extend from the magnetotail down to the polar ionosphere. At Titan, both the photoionization source and the electron impact ionization source contribute to the formation of the ionosphere. The ionizing electrons at Titan originate in the nearby magnetosphere of Saturn and follow the magnetic

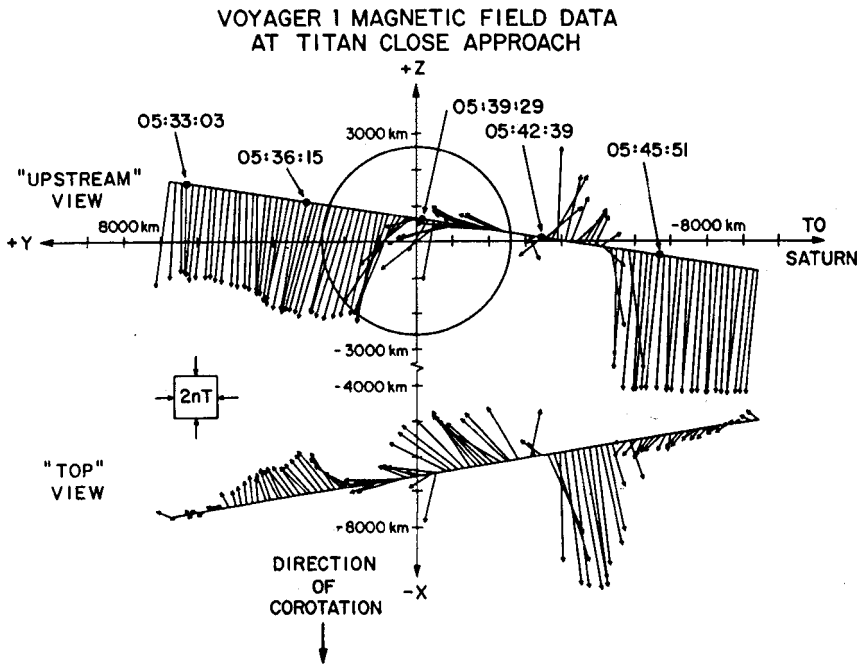

Figure 1. Projections of measured magnetic field vectors on two planes are shown along the Voyager 1 trajectory during its encounter with Titan's plasma wake. (From Ness *et al* (1982), © 1982 American Geophysical Union.)

field lines down into Titan's upper atmosphere. These electrons are hot, with thermal energies of about 200 eV. The relative proportion of the two ionization mechanisms (EUV or magnetospheric electrons) at a particular location on Titan and at a particular time is a complicated function of altitude, latitude and longitude, and orbital position of Titan.

Many different ion species are produced by ionization processes in Titan's upper atmosphere. The ion production rates are highest for the following species: N_2^+, N^+, CH_4^+ and CH_3^+. The overall ion production rate has a maximum at an altitude (above Titan's surface) of about 1100 km. This is the altitude where the optical depth for the incoming EUV radiation, or for the magnetospheric electron 'beam', is unity. Optical depth is the probability of absorption and is proportional to both the column density of absorbing atmospheric constituent and to the absorption cross section. In the main ionospheric region (altitudes between about 1000 km and 1700 km), the neutral density is high enough that ionization and chemical processes determine the distribution of ion species. The electron density at any location is equal to the sum of the ion densities of all ion species, because the plasma must remain charge neutral to an extremely high degree. N_2^+, CH_4^+ and CH_3^+ ions which are originally produced by ionization processes are quickly converted by ion–neutral chemical reactions to a variety of other ion species. These other species include hydrocarbon species as $C_2H_5^+$ and CH_5^+ and nitrile species such as $HCNH^+$. These molecular ion species then recombine with the thermal ionospheric electrons via dissociative recombination reactions. For example, $C_2H_5^+$ ions are produced from CH_3^+ ions via reaction with methane, and $C_2H_5^+$ in turn reacts with hydrogen cyanide (HCN) producing $HCNH^+$. $HCNH^+$ can further react with the neutral hydrocarbon C_4H_2, producing even heavier hydrocarbon ion species, or it can dissociatively recombine. Two of the more important chemical reactions can be represented by

$$C_2H_5^+ + HCN \longrightarrow HCNH^+ + C_2H_4$$

$$HCNH^+ + e \longrightarrow HCN + H.$$

The full ion chemistry scheme for Titan's ionosphere is quite complex and is not yet well understood.

The ionospheric electron density profile measured near the dawn terminator (i.e. the day–night boundary) by the Voyager spacecraft using the radio occultation technique had a peak density of 2400 cm^{-3} (with a possible uncertainty of 1100 cm^{-3}), and the peak was located at an altitude of 1180 km (with an uncertainty of 150 km). These values are in reasonable agreement with theoretical models which incorporate known ion sources and known chemical processes.

For altitudes above about 1700 km, where the neutral density is rather low, plasma transport associated with rapid flow becomes more important than chemical processes in controlling the distribution of ionospheric plasma. This flow is driven mainly by the interaction of the ionosphere with the external magnetospheric

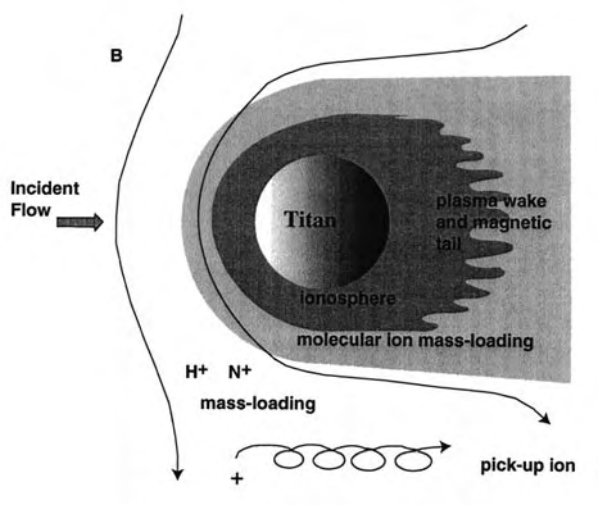

Figure 2. Schematic representation of the interaction of Titan's exosphere and ionosphere with the Saturnian magnetospheric plasma which is being convected from the left of the diagram. The external flow is mass-loaded with ions created by ionization of Titan's exospheric neutrals, such that the flow is slowed down and the magnetic field becomes draped around the satellite. (Adapted from Keller *et al* (1992).)

plasma. *In situ* measurements were made by the Voyager 1 spacecraft in the plasma wake region at a radial distance of about $2.7R_T$. The plasma seen by Voyager was much denser, colder and slower than the external magnetospheric plasma, yet was less dense, hotter and slower than the plasma deep in the ionosphere. The measured flow speeds were a few kilometers per second and the ion temperatures were such that typical thermal energies were a few eV. The total ion density was about 30 cm^{-3}. The major ion species had a mass of about 28 atomic mass units (making it either N_2^+, $HCNH^+$ or some similar species). Measurements of the upper hybrid resonance (a type of plasma wave) also indicated the existence of a cold (temperature, T_e, of a few eV) electron population with a maximum electron density of 39 cm^{-3}. The wake plasma appears to be an extension of the ionosphere and is probably transported outward from the main ionosphere.

Interaction of Titan with Saturn's magnetosphere

We now reconsider the interaction of Titan's atmosphere and ionosphere with Saturn's magnetosphere. The plasma conditions near Titan in Saturn's outer magnetosphere are quite variable (see SATURN: MAGNETOSPHERE). At the time of the Voyager 1 encounter, the magnetospheric plasma incident on Titan had H^+ and N^+ densities of $\approx$0.1 cm^{-3} and 0.2 cm^{-3} respectively, an N^+ temperature of about 3 keV (this is really a thermal energy and the corresponding temperature is about 3×10^7 K), and a flow speed of approximately 120 km s^{-1} relative to Titan (see table 1). This flow speed is less than the full co-rotation speed of about 200 km s^{-1}. The co-rotation speed is that speed, as a function of distance from Saturn, which is needed for the all the magnetospheric plasma to move around the planet with the same rotational frequency. The high temperature, the presence of N^+ and the flow speed less than the full co-rotation speed are all indications that a fair fraction of the plasma in Saturn's outer magnetosphere has come from Titan itself, no doubt from previous encounters. Plasma is apparently added to the magnetosphere of Saturn in the near vicinity of Titan from ionization of the exosphere, or from direct escape out the plasma wake, and also in a very extended region by ionization of the extensive neutral torus which exists throughout a significant part of the outer magnetosphere. The torus is formed from neutrals which have escaped from Titan.

Table 1. Properties of Saturn's magnetospheric plasma flow upstream of Titan determined by Voyager 1. (Adapted from Neubauer *et al* (1984).)

Magnetic field strength (B)	5 nT
Plasma flow speed	120 km s^{-1}
Proton number density	0.1 cm^{-3}
N^+ number density	0.2 cm^{-3}
Electron number density	0.3 cm^{-3}
Proton temperature	210 eV ($\approx 10^6$ K)†
N^+ temperature	2.9 keV
Electron temperature	200 eV
Sound speed	210 km s^{-1}
Alfvén speed	64 km s^{-1}
Magnetosonic/fast mode speed	220 km s^{-1}
Magnetosonic/fast mode Mach number	0.55
Alfvénic Mach number	1.9
Thermal proton gyroradius	413 km
Thermal N^+ gyroradius	5790 km ($\approx 2R_T$)

† Note that 1 electron volt (eV) is 1.602×10^{-19} J and 1 keV = 1000 eV. Also note that thermal energy $\approx kT$ where k is Boltzmann's constant and T is temperature.

The plasma flow incident on Titan at the time of the Voyager encounter (table 1) was subsonic ($M_s < 1$) and submagnetosonic ($M_f < 1$), yet super-Alfvénic ($M_A > 1$), which distinguishes this interaction from other examples of plasma interactions with non-magnetic bodies. For example, the solar wind is supersonic and supermagnetosonic. Jupiter's magnetospheric plasma impinges on its satellite Io as both a subsonic and a sub-Alfvénic flow (see IO: PLASMA TORUS, MAGNETOSPHERES: JUPITER, SATELLITE INTERACTIONS). A Mach number is the ratio of a flow speed to a characteristic wave speed in a fluid medium. For a magnetized plasma the relevant wave modes are sound waves (propagation of pressure disturbances), Alfvén waves (propagation of magnetic disturbances) and magnetosonic waves (also called fast mode waves). Magnetosonic waves are the propagation of combined magnetic and pressure disturbances.

Putting aside for the moment the question of how Titan acts as an obstacle, one difference between Titan's interaction and the solar wind interaction with non-magnetic bodies such as Venus or comets is that the

Dirac House, Temple Back, Bristol, BS1 6BE, UK

solar wind, unlike Saturn's plasma, is supersonic and supermagnetosonic. When a fluid approaches a body (that is, an obstacle) at subsonic speeds, sound waves are able to communicate the existence of the body out into the approaching fluid, so that the flow is able to adjust gradually and is able to smoothly flow around the body. However, when a supersonic flow (or supermagnetosonic flow for a plasma) encounters an obstacle, a shock wave forms upstream of the obstacle. A shock wave is a very thin layer across which the fluid properties change suddenly. The flow speed decreases and the density and temperature both increase as a fluid goes from upstream to downstream of a shock front. Bow shocks have been observed in the supersonic and super-Alfvénic solar wind flow upstream of all the planets in the solar system (except Pluto), as well as in the solar wind upstream of COMET HALLEY and COMET GIACOBINI–ZINNER. However, because Saturn's plasma encounters Titan at a submagnetosonic speed (at least at the time of the Voyager encounter), a bow shock is not expected in this case and, in fact, was not observed by any of the Voyager 1 plasma and field experiments. Numerical magnetohydrodynamic (MHD) models of this interaction confirm this feature of the magnetospheric interaction with Titan.

What is the nature of the obstacle that Titan presents to the external plasma flow? What determines the type of interaction? Why is Saturn's magnetic field draped around Titan? The atmosphere and ionosphere of any non-magnetic body present an obstacle to an external flow. The nature of this interaction depends on the characteristics of the object and on the nature of the external flow. The solar wind interactions with comets and Venus represent extreme cases of how this can happen (see SOLAR WIND: INTERACTION WITH COMETS, VENUS: INTERACTION WITH SOLAR WIND). The mass-loading process dominates the cometary interaction, whereas the ionospheric pressure force is the most important factor for Venus. Both seem to be important near Titan. First, consider the important mass-loading process.

Ions which are newly created in a plasma flow must somehow be assimilated into that flow. A charged particle moves in a circular trajectory in a uniform magnetic field if the background plasma is stationary. The radius of this circle is called the gyroradius. The gyroradius increases with increasing particle mass and with increasing particle speed. For example, the N^+ ions observed in Saturn's outer magnetosphere are fast enough that their gyroradii are roughly the size of Titan. H^+ ions near Titan have smaller gyroradii. When ions are created in a magnetized flowing plasma, their motion is a superposition of both gyromotion and drift motion in the direction of the background plasma flow. This is called ion pick-up. Associated with ion pick-up is a process called mass-loading, which appears to be operating near Titan, as well as near comets. The addition of mass to a fluid will slow down the fluid, in order for momentum to be conserved. The ion pick-up and mass-loading at Titan mainly consists of molecular ions close to that satellite and atomic ions further away (figure 2), reflecting the radial variation of the neutral composition.

The slowing down of a magnetized and flowing plasma, whether due to mass-loading or due to the other dynamical processes, affects the magnetic field in the plasma. Magnetic fields are 'frozen into' any fluid, such as most plasmas, which have high electrical conductivity. In this case, a piece of field line stays attached to a particular parcel of fluid. Hence, if the flow is slower in one region, such as near an obstacle or in a mass-loaded region, yet remains rapid elsewhere, the result is the draping of the magnetic field lines around the obstacle, with the associated formation of a magnetotail.

The interaction of the solar wind with comets is primarily determined by the mass-loading process. The nucleus of a comet is typically only a few kilometres in extent and is made of ice and dirt. The neutral gas (mainly water vapor) produced by the nucleus is not restrained by gravity and forms an atmosphere (or coma) that extends more than 10^5 km into interplanetary space. These neutrals are ionized by solar EUV radiation and the newly created ions are 'picked up' by the solar wind. On the other hand, the interaction of the solar wind with Venus takes place mainly near the planet. Mass-loading plays a relatively minor role in the Venus interaction. The ionosphere itself acts as the main obstacle to the solar wind flow. Ionospheric plasma is an excellent electrical conductor, and the solar wind induces electrical currents in the ionosphere that act to largely exclude the solar wind plasma with its imbedded interplanetary magnetic field. The magnetic field strength builds up as the flow approaches the ionosphere, resulting in the formation of a magnetic barrier located outside the ionopause. The ionopause is the boundary between the cold, dense ionospheric plasma and the hotter magnetized solar wind plasma. At the ionopause, the ionospheric thermal pressure balances the solar wind pressure, which mainly consists of magnetic pressure in the magnetic barrier. In fact, this pressure balance determines the location of the ionopause. As the solar wind pressure increases, the ionopause moves to lower altitudes where the ionospheric pressure is greater.

Ordinarily, for time periods when the solar wind dynamic pressure is significantly less than the maximum ionospheric thermal pressure, the ionosphere of Venus remains virtually field-free and the ionopause is a sharp boundary. However, at other times, when the external pressure exceeded the maximum ionospheric pressure, the ionosphere of Venus was observed by the magnetometer on board the Pioneer Venus Orbiter to be permeated by large-scale magnetic fields. In this case, the ionopause was much broader and less distinct, and was located at lower altitudes. The interaction of the solar wind with Mars seems to be similar to the Venus-like interaction for high solar wind dynamic pressure conditions, although mass-loading processes appear to make some contribution at Mars.

What about the interaction of the external plasma with Titan? The exosphere of Titan is rather extensive, resulting in some comet-like mass-loading, but there is also a substantial ionosphere, so that the Venus-like interaction scenario also applies to some extent. The Titan interaction appears to be a hybrid between a comet-type interaction and a Venus-type interaction. A magnetic barrier and a draped-field magnetotail are part of all these interaction scenarios. Will an ionopause boundary exist at Titan, just as it does at Venus? The total external plasma pressure upstream of Titan, including dynamic, thermal and magnetic pressure (which can be found from the parameters listed in table 1), is approximately $p_{\rm ext} \approx 10^{-9}$ dyn cm^{-2}. The maximum ionospheric pressure can be estimated to be $p_{\rm ionos} = 0.95 \times 10^{-9}$ dyn cm^{-2} at an altitude of 1150 km for daytime conditions. Hence the ionospheric and the external pressure are comparable, leading us to believe that, although the ionospheric pressure plays a very important role in the interaction, the external magnetic field will push its way deep into the ionosphere. The ionopause will be very broad, indistinct and located at a low altitude, and the ionosphere should be permeated with magnetic field. The proper analogy is Venus for high solar wind pressure conditions but with a significant amount of mass-loading also taking place.

Much remains to be learned about how Titan interacts with Saturn's magnetosphere. The next major advance in our understanding will come from the CASSINI MISSION, which was developed by NASA and ESA. The Cassini spacecraft was successfully launched in October 1997, and will arrive at Saturn in 2004. After insertion into orbit around Saturn, the Cassini Orbiter will encounter Titan many times.

Saturn: Rings

Saturn's magnificent ring system is unique, with uncountable billions of icy particles in orbit around the planet. They represent a fundamental class of planetary structure. In this way, the studies of Saturn's rings may be crucial to one of the fundamental objectives of planetary science: to understand the origin and the evolution of the planetary systems. The aim of this article will be to emphasize general aspects of the structure of Saturn's rings.

The outer planet SATURN symbolizes all the planets. Its beautiful rings, discovered in the 17th century, give it a unique majesty, and whoever has seen Saturn through a moderately large telescope is not likely to forget the experience. As revealed by Pioneer and Voyager spacecraft and more recently by the Hubble Space Telescope, the rings are unbelievably dynamic and complex. The wealth of knowledge about Saturn's rings accumulated over 300 yr, with special attention paid to the cascade of data obtained by VOYAGER, is summarized according to the following steps.

The questions of the origin and of the evolutionary processes are directly correlated with the properties of individual ring particles. These properties include composition, nature of surface and particle size distribution; they will be discussed after the presentation of a brief history of the very exciting discovery of Saturn's rings.

The structural features, at whatever scale the rings were observed, posed great challenges to scientists to construct new dynamic theories. Some of these features have been explained from previous work in galactic and stellar dynamics. However, the rings remain extremely useful to astronomers, because some of the unexplained dynamic processes operating in the present ring may be similar to processes that occurred in the early ACCRETION DISKS. We will describe in a particular section the major dynamic phenomena which sculpt the rings.

The rings show many youthful features, raising the problem of their age and their origin. The problem is essentially this: calculated lifetimes for phenomena that are now occurring in the rings are considerably less than the age of the solar system. A review of the theories proposed to explain the formation of the rings will be presented. We will end with current and future developments.

History of their discovery

Considerable controversy resulted from the precise nature of the appendages of Saturn first observed by Galileo in 1610. Was Saturn grossly oblate? Were there two giant satellites? CHRISTIAAN HUYGENS revealed in 1659 that they were parts of a ring that surrounded Saturn whose diameter was more than twice Saturn's. The anagram being a common method of publishing among scientists in the seventeenth century, he announced his discovery as the following anagram: AAAAAAA CCCCC D EEEEE G H IIIIII LLLL MM NNNNNNNNN OOOO PP Q RR S TTTTT UUUUU, meaning *Annulo cingitur, tenui, plano, nusquam cohaerente, ad eclipticam inclinato* (He is surrounded by a thin flat ring, which does not touch him anywhere and is inclined to the ecliptic).

Huygen's speculation, that the ring was monolithic, became more controversial after JEAN DOMINIQUE CASSINI's observation of a gap in Huygen's single ring in 1675; this gap is now known as the *Cassini Division*. PIERRE SIMON DE LAPLACE began in 1787 dynamic studies on the ring system and concluded that the planet was surrounded by a large number of narrow solid rings. During the first part of the 19th century, Laplace's vision was generally accepted, and it inspired some observers to report faint additional divisions of the rings that could not be confirmed later.

In 1849, EDOUARD ROCHE determined the minimum distance at which a satellite influenced by its own gravitation and by its planet can exist; in the case of Saturn, if the planet and the satellites have equal density, the satellite cannot come closer than 2.44 times the radius of the planet without being broken up. He noted that this distance is 'à peine supérieure au rayon extérieur de l'anneau de Saturne' (a little farther than the external radius of Saturn's rings). This result was later known as the 'Roche limit' and began to discredit the idea of solid rings.

Finally, a series of dynamical studies followed, culminating in JAMES CLERK MAXWELL's classic essay of 1857, after which no theoretical doubt remained that Saturn's rings could only consist of an indefinite number of very small particles. Only much later (in 1895) did observations confirm the theory, when JAMES KEELER spectrographically measured the Doppler shift of the particles.

The discovery of new rings around Saturn (and around Jupiter, Uranus and Neptune (see PLANETARY RINGS)) has been a major finding of the past 30 yr, and has been the result of spacecraft- and ground-based observations. In 1967, Feibelman first reported photographic evidence of a wide outer ring (now called the E ring) encompassing the orbits of the satellites Mimas, Enceladus, Tethys and Dione (see SATURN: SATELLITES).

A narrow ring (called the F ring) lying a few thousand kilometers beyond the outer edge of the common broad Saturnian ring was detected by Pioneer 11 in 1979.

From the early 1970s, numerous astronomers attempted to identify some material within the main rings. However, only Voyager spacecraft were able to distinguish the presence of material between the C ring and the planet. This material came to be identified as the D ring.

Of all of the Saturnian rings given a letter designation, the latest and the least known is the G ring. Its presence was detected by Pioneer 11 through its absorption of several charged particles and visually confirmed by Voyager 2.

Overview of the remarkable rings

The rings fall into two main categories, depending on their optical depth τ, which measures the average number of particles that a light ray perpendicular to the ring would go through.

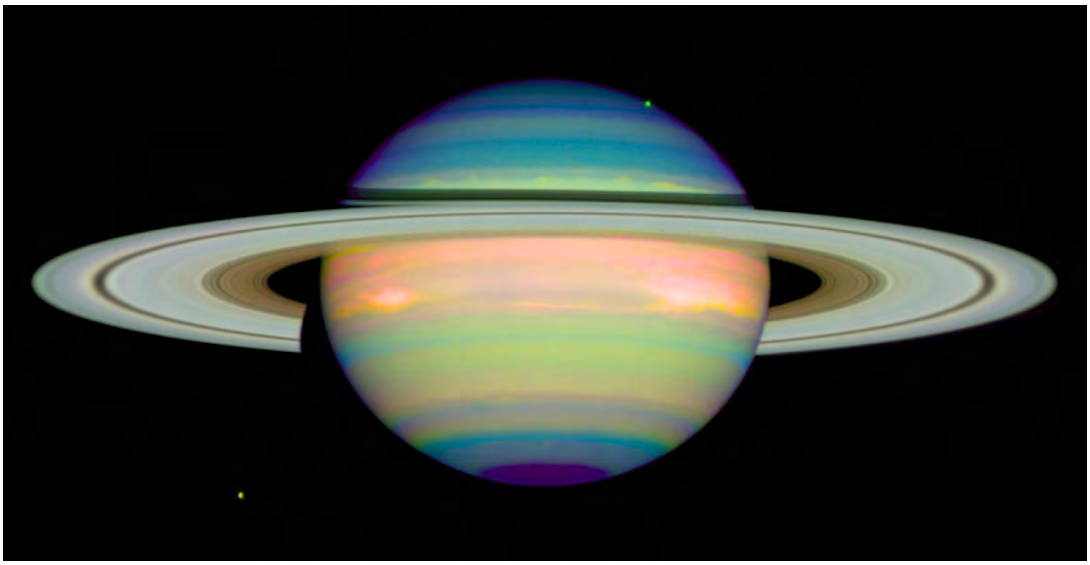

Figure 1. The main ring system. Saturn's main ring system taken by the Hubble Space Telescope. Moving radially out from Saturn, we see the general areas which are the C ring, the B ring, the Cassini Division and the A ring. The rings cast their shadow onto Saturn. The C ring and the Cassini Division are significantly darker than the A ring; the B ring is slightly brighter. The bright line seen within this shadow is sunlight shining through the Cassini Division. Two of Saturn's satellites were recorded, Dione on the lower left and Tethys on the upper right. Tethys is just ending its transit across the disk of Saturn. **This figure is reproduced as Color Plate 43.**

The main rings (C ring, B ring, Cassini Division and A ring), displayed in figure 1, are located within or near the Roche limit and have $0.05 < \tau < 2.5$. The total mass of these rings is approximately that of the satellite MIMAS, which has a radius of 200 km. All observations imply that the main rings' particles are primarily water ice, but there is evidence of some ALBEDO and therefore some compositional variation within the ring system. Most of the particles are in the 1 cm–5 m size range, but wave structures detected by Voyager spacecraft are strong indicators that small satellites with radii ∼10 km also exist. The motion of a particle is determined, to a first approximation, by the gravitational influence of the planet. To a much lesser extent, the gravity exerted by Saturn's satellites and the other ring particles and the collisions between particles disturb the orbit.

By contrast, the G and E rings (see figure 2) and the D ring are tenuous ($\tau < 10^{-4}$) and consist primarily of micrometer-sized particles. These rings are distinguished in two fundamental ways from the major Saturnian rings: single-particle dynamics (dominated by Saturn's gravity, solar radiation pressure and electromagnetic forces), rather than collective effects, probably govern their form and the majority of particles have quite limited lifetimes ($<10^4$ yr). The smaller particles, less than 1 cm in radius, would indeed be quickly removed from the Saturnian environment by falling onto the planet or ejected outwards. These particles must be replenished by some source within the rings.

The F ring ($\tau \sim 0.1$) is intermediate in properties between the main rings and tenuous rings. It is a narrow, inclined, multistranded ring lying 3400 km beyond the edge of the main ring system and shows a remarkable degree of longitudinal variation, including clumps, kinks and braided structures (see figure 3). Data on Saturn's rings are given in table 1.

Rings: a myriad of small satellites

Saturn's rings are composed of a myriad of individual particles. However, even in the post-Voyager era, no individual particle has been seen yet. The basic properties of individual particles can be constrained by reflected sunlight, thermal emission and radar reflectivity. Specifically, ground-based and spatial observations from ultraviolet (10^{-5} cm) to radio (10 cm) wavelengths contain crucial information on the ring properties. Because the rings comprise an ensemble of particles acting collectively, radiative transfer relates the ring properties to some intrinsic particle properties such as the composition, the size and the physical nature.

Composition of the particles

Near-infrared spectral data (1–2.5 μm) of the main rings were used to establish that water ice is a major component of the ring material. The decrease in reflectivity from the visible to the ultraviolet indicates that something other than pure water ice (probably silicates) is present, the non-icy component making up less than about 10% of the rings.

The tenuous rings are spectrally resolved with difficulty. However, recent observations during the 1995 Earth ring plane crossings show that the spectra of the E and F rings are clearly bluish, different from the main rings and from most of the solar system objects, which are

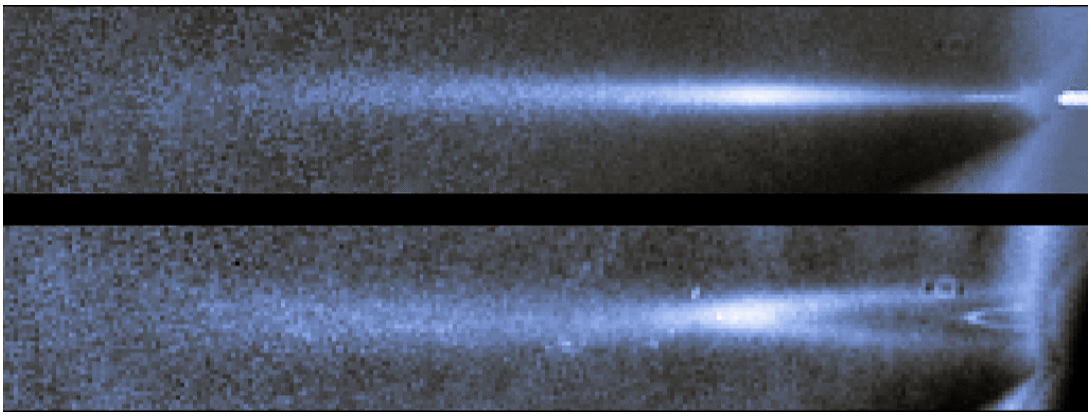

Figure 2. The tenuous E and G rings. Two images of the east ansa of the E and G rings, taken near the Earth August 1995 ring plane crossing (top) and near the Sun November 1995 ring plane crossing (bottom) with the Hubble Space Telescope. The planet Saturn, not visible, is on the right side. The two images cover the same region ranging approximately from 2.5 to 8 Saturn radii. The G ring appears as a thin bright line extending beyond the edge-on main rings in August but it is visible more distinctly in November, when the rings are inclined. The E ring is seen as a line extending beyond the G ring. The E ring peaks at the satellite Enceladus.

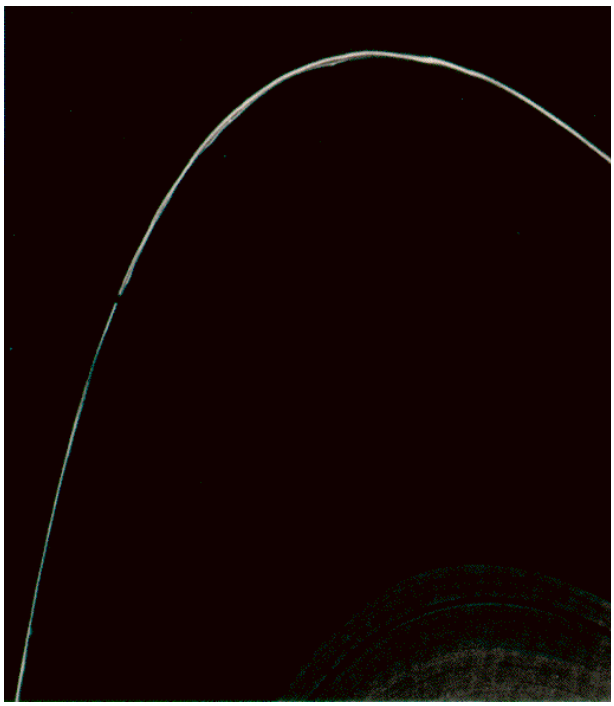

Figure 3. The strange F ring. One section of the strange F ring viewed by Voyager 1 showed braids, clumps of matter and kinks. Nine months latter, Voyager 2 revealed that the structures were gone.

Figure 4. Radial structures of the rings. Voyager 1 obtained this spectacular view of the crescent Saturn and its rings from a distance of about 1.5 million kilometers. Typical structures in the rings vary. Going outwards from the innermost visible ring, we first encounter the C ring characterized by a broad platform. Then, the B ring dominated by irregular structures. The Cassini Division is a region of low optical thickness. The A ring is almost featureless. The Encke gap can clearly be seen in the outer part of the A ring. Finally, the F ring is visible like a pencil line circumscribing the main rings.

reddish. More detailed analysis is needed to indicate their particle composition.

Size and physical nature of the particles

Our understanding of the sizes of the main rings' particles comes principally from radio measurements of the brightness temperature and the radar reflectivity of the rings. Observations at these millimeter to centimeter wavelengths indicate that most of the surface area of the ring must be filled with particles whose radii lie between a few centimeters and a few meters. Very little micrometer-sized dust is present. Small moonlets (10–100 m radius)

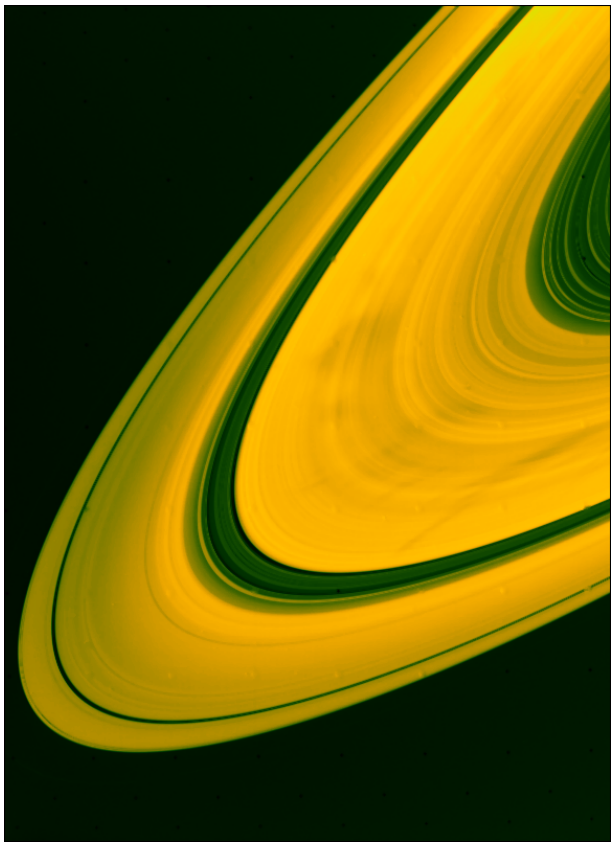

Figure 5. Spokes. The dark spokes in the B ring can be seen in this Voyager 2 picture by reflected light. They are made of small particles (about 1 micrometer), which do not reflect the light properly.

have been invoked to explain some irregular structures such as gaps and narrow ringlets. One satellite, Pan (∼10 km), has been discovered within the A ring.

Although the rings are inside the Roche limit, particles can gravitationally be bound onto the surfaces of larger ones, and particle collisions should produce accretion in Saturn's rings, especially in the A ring. The process of accretion can be counterbalanced by tidal disruption, so that complex, aggregate, fluffy particles (dynamical ephemeral bodies (DEBs)) may exist. Recent studies indicate that aggregates of microscopic particles, gathered in weak clusters of a few centimeters to a few meters, could explain the spectroscopic properties. These results seem to support the DEB model of ring particles, but further studies are required.

The E ring particle size distribution is dominated by microscopic particles: a narrow size range centered near 1 μm radius dominates its brightness. The G ring contains a large range of particle size which goes from dust particles to kilometer-sized bodies.

The very strange morphology of the F ring is not easy to interpret and could be due to its position near the Roche limit, which would imply a very broad particle size range. Voyager detected a narrow core (a few kilometers in width) of centimeter-sized particles, with an inward envelope (some 10 km in width) of micrometer-sized particles. Both the F and G rings must also contain a certain number of moonlets, roughly 1 km in size, to supply the smallest particles and to explain some azimuthal variations.

Ring structures

Disks and rings are a natural consequence of dissipation in rotating systems. A cloud of debris surrounding an oblate planet settles very quickly into a flat circular ring in the equatorial plane because of collisions between the particles. Subsequently, a spreading process occurs on a time scale much larger than that of the flattening process.

Eventually, the traditional image of a ring is that of a set of particles in orbit around a planet undergoing mutual collisions and making up a structure with perfect circular symmetry and ill-defined edges. However, Voyager probes and the most recent ground-based observations revealed several surprising structural features (see figure 4): eccentric shapes and inclined orientations; sharp edges; azimuthal variations, arcs, clumps, kinked and braided configurations; waves. We will now discuss some major structures by describing the phenomena which create them.

Gaps and narrow rings

The fact that the rings have sharp edges rather than diffuse ones, as well as the presence of thousands of narrow rings clearly separated by gaps, indicates that some mechanism confines the particles. Through gravity, a nearby satellite will alter a ring particle's orbit, making it elliptical. This effect is especially pronounced when there is a resonance between the ring particle and the satellite (a resonance occurs when the orbital periods of the ring particles are commensurate with the period of the satellite by a ratio of integers). The resonant perturbations on a population of ring particles increase the density in some places and decrease it in other places. Because of the collisions, the theory shows that there is a repulsion between part of the ring and the satellite, leading to the creation of a gap in the disk. For instance, the small moon Pan has been discovered in the Encke gap. If the forcing satellite is external to the ring system and close to it, a sharp edge will form accordingly. The process is clearly illustrated in the A ring, where a sharp edge is seen at a Janus resonance, which marks the outer edge of the ring.

Strange narrow and eccentric features are present in the C ring, the Cassini Division and the Encke gap. These ringlets are surrounded by two gaps. In some cases, such as the Encke gap, the ringlet can only be seen at some ring longitudes and may consist of dust on 'horseshoe orbits' which has been ejected from the moonlet Pan. By contrast, the formation of some structures remains unexplained.

Azimuthal variations

Narrow rings in the Encke gap exhibit strong azimuthal brightness variations. However, the most striking phenomenon is undoubtedly the F ring, located near the Roche limit. Voyager images indeed showed some condensations up to about 5 km in radius within the rings. The F ring is surrounded by two moons (Pandora and Prometheus) orbiting on either side of the ring and called the 'shepherd' satellites. The strange appearance of the F ring suggests that moons–F ring interplay has some importance, but the confinement of this ring remains unexplained.

A moon in an eccentric orbit induces variations in semimajor axes of the ring particles. As a result, the ring particles tend to crowd into clumps. Some observed condensations are indeed roughly consistent with those induced by gravitational influence of the two moons. The clumps or arcs could also be explained through resonances between particles and moons, which confine the ring particles. Unfortunately, collisions between the ring particles tend to smooth the clumps, so that it is not clear whether these features would be detectable. The existence of small (radius <10 km) moons within the F ring has been postulated by several authors, because an embedded moon may provide a source for the condensations. However, no moon has been seen yet. So, it is not clear whether the clumpy structures are individual solid objects embedded in the ring or just enhancements in the local surface density due to the perturbation of the shepherd satellites. Further theoretical and observational studies are required to answer the fundamental questions of confinement of ring particles by moons.

Waves

Among the most intriguing phenomena observed by Voyager were the spiral waves. Observations and dynamical theories have identified two kinds of spiral waveforms: density waves and bending waves. Density waves are spiral patterns of enhancement and depletion of ring materials. Bending waves are vertical undulations of the disk, formed by inclined orbits of particles.

A wave is the oscillatory response of the disk associated with a satellite resonance. Saturn has several known satellites inside the orbit of Mimas (see table 1). Satellites in eccentric and inclined orbits supply periodic horizontal and vertical perturbations to ring particles at resonance locations. The displacement of particles away from their circular orbits perturbs the gravity field in the immediate area. The self-gravity of the aggregation of ring particles allows the perturbations to propagate away from resonance locations, leading to the formation of spiral (density or bending) waves.

Waves are most common in the A ring. The waves are signatures of a number of physical properties: mass density, viscosity, vertical thickness. As an example, the total mass of Saturn's rings could be estimated to be about the same as its moon Mimas by inferring the dynamic response of the rings to the waves.

Meteoritic bombardment

Soon after the spectacular imaging observations of the ring systems at the Saturn encounter by Voyager, it was quickly recognized that the formation and structure of the rings must be closely coupled to the interplanetary meteoroid complex via collisional interactions. The basic idea is that hypervelocity meteoroid impacts create EJECTA, which are reabsorbed by the ring plane. Continuous exchange of ejecta between different ring regions causes mass transport from one region of the ring to another. In particular, the bombardment may help to sharpen the inner edges of the A and B rings, which cannot be done by resonances.

Another physical consequence of the meteoroid–ring impact would be the generation of ring atmosphere. Moreover, in some theoretical models elaborated from the rings–meteoroid interaction, the lifetime of the rings was estimated to be as short as a few million years. While such estimates have large uncertainties, they underline the importance of the meteoritic bombardement in shaping the ring dynamics.

Spokes

Thirty-seven days before its closest approach to Saturn, Voyager 1 discovered dark, nearly radial features in Saturn's B ring; these finger-like markings are called spokes, visible in figure 5. These dark clouds are about 8000 km long and 2000 km wide, develop in several minutes, follow the rotation of the rings and disappear several hours later. In fact, the spokes appear dark in reflected light and bright in scattered light, indicating that they are made of micrometer particles. These small particles are thus most easily moved by electric and magnetic forces. These properties point to a mechanism coupling the dynamics of ring particles with electromagnetic phenomena in the magnetosphere and have prompted several scenarios to explaining the spokes' formation. The most advanced one is that the spokes are the result of meteoroid impacts onto the rings, producing a plasma. Lorentz forces from Saturn's magnetic field force the plasma into a radial direction, which electrostatically levitates small ring particles, leading to the formation of spokes. In another theory, it would be an electron beam originating in the upper magnetosphere, which could hit the ring and charge the dust grains. One alternative possibility is that spokes are the manifestation of compressional waves (called also magnetosonic waves) in the partly ionized ring disk in Keplerian rotation, embedded in the vertical magnetic field of the planet. However, none of these scenarios is fully satisfactory.

Dusty rings

The dusty D, E, F and G rings tend to have very brief lifetimes owing to a variety of physical processes: drag forces, such as plasma and Poynting–Robertson drag, sweep material out of the ring, while destruction mechanisms, including magnetospheric and meteoroid impacts, eliminate dust grains in place. The dust observed must therefore be replenished by some nearby source,

Enceladus	238 040	33	–	–	8.5×10^{22}

[a] Radial distance is the boundaries for the rings, semimajor axis for the satellites.

[b] Particle size is range of typical radii for ring particles, mean radius for the satellites.

[c] Pan orbits inside the Encke gap.

[d] The E ring is very broad, but densest near the orbit of Saturn's moon Enceladus.

either seen or unseen. Sources of the dust are meteoroid impacts onto moons and large ring particles and collisions between ring particles which release regolith material. The dust content within the rings is then determined by a balance between collisional and meteoroid excavation of dust, as sources, and sweep-up and loss from the rings by drag and magnetic field, as sinks. The typical dusty ring model considers two distributions of particles: one includes the large particles which are responsible for the production of dust, the other the dust particles. The balance between dust loss and dust production allows us to determine the population of the large bodies. For instance, it is proposed that the G ring is formed by a dusty population of short-lived particles continuously maintained by a belt of large bodies of roughly 1 km in size.

Age and origin of the main rings

The main rings appear to result from a similar process to that which created regular satellites. Their orbits are prograde, equatorial and nearly circular. A question that immediately arises is whether they are the uncoagulated remnants of satellites which failed to form because of the tidal forces or the result of a disruption of pre-existing objects. In fact, evolutionary processes with time scales considerably smaller than that of the solar system appear to affect the ring systems. Because of these short time scales, rings would not form with their primary planets but could be created later by disruption of satellites.

Age of the rings

The high albedos of the main rings' particles seem to imply that the rings lack dark impurities. Over the age of the solar system, the rings should have been struck by roughly 0.1–1 times their mass in meteoritic material. So, if the rings existed from the origin of the solar system, they should be much darker than they are at present. In particular, the impacts of dark micrometeoroids onto the B ring should have darkened the particles to their present albedo in only 100 million yr. This darkening time is comparable with the evolution time inferred for the main rings from mass loss by erosion.

An independent short time scale argument comes from the evolution of the small moons near the rings. The moons which have resonances with rings pull angular momentum out of the ring system and, therefore, should evolve outward. For example, the transfer of angular momentum between rings and moons would move the satellite Prometheus the same distance it has already moved from the edge of the A ring in several million years. Neither the moons nor the rings could then maintain their present positions for more than about 10 million yr.

Origin scenarios

Since many workers in the field now look at rings as systems which cannot survive for longer than 10–100 million yr, the rings must be created and recreated many times over the age of the solar system. In the recent-origin models, the rings are created by the breaking up of some other body, either by cometary impact on one of the nearby moons of Saturn or by tidal disruption of a large comet which passed close to the planet.

The lifetime of a moon before a catastrophic disruption depends on its size and on the bombardment flux. The bombardment flux has varied during the age of the solar system. It is smaller in the current epoch

than during the early phase, so that the expected lifetime for a moon 200 km in radius is close to the age of the solar system: the creation of Saturn's rings in the last 100 million yr is therefore an improbable event. A similar alternative involving tidal disruption of a large comet suffering a close encounter with the planet, has been discussed, but it appears to be equally unlikely.

Current understanding favors the destruction model in which the Saturnian ring system is derivative. However, it is especially difficult to explain, because of its large mass and compositional purity. Clearly, considerable effort needs to be devoted to this.

Prospects for the future

The complicated physical and dynamical processes involved in the generation of Saturn's rings require further studies and observations. The recent observations of the 1995 ring plane crossings and the upcoming Cassini mission to Saturn should be able to yield new knowledge on the ring system.

New results and challenges from 1995 ring plane crossings observations

The most spectacular ring system of the outer planet can also be a nuisance for the detection of faint material lying close to the main rings. Huygens was the first who realized that Saturn's ring system appears to vanish twice every orbital period of 30 yr as the Earth crosses the ring plane and that the rings are viewed edge on. The last crossing through Saturn's ring plane during 1995–1996 has provided the best opportunity to observe the faint E, F and G rings and small satellites from Earth until the year 2009.

The structure and particle properties of the E ring were constrained by new photometric observations, from the UV (0.3 μm) to the near infrared (2.2 μm). These observations continued to indicate a fairly narrow particle size centered around 1 μm radius. This predominance of such a narrow-size particle is unique in planetary rings and confirms that the ring may be self-sustained by collisions between E ring particles and the satellite ENCELADUS. A puzzle is the absence of localized peaks associated with other icy moons.

The 1995 campaign captured stunning new images of the G ring. Its intensity and inferred optical depth show the G ring to be a region where many large particles are present. This supports the idea that the G ring was formed by the disruption of a progenitor satellite. So, the observations of E and G rings are in fair agreement with previous spacecraft data, but photometric analysis and modeling should continue.

The most surprising result was that a few teams have detected several never-before-seen bodies in the vicinity of the F ring. First studies indicated that these bodies are not new satellites but more probably transient clumps or arcs within the F ring. These discoveries are more interesting than finding new satellites, because the dynamical processes sculpting these objects probably occurred when many of the planets first formed moons and rings. An explanation of these phenomena would constrain the processes of accretion in the early solar system. The other very interesting and puzzling result to come out of the ring plane crossing data is the 1 h lag of the satellite Prometheus behind its expected position. This lag actually challenges celestial mechanics and seems to reflect the importance of the moon–ring interaction.

The Cassini/Huygens mission

The CASSINI/HUYGENS MISSION is a 4 yr, close-up study of the Saturnian system. It will begin in 2004 and include the planet's atmosphere and magnetic field, several moons and of course the rings. As the best-instrumented probe ever sent to another planet, Cassini will produce the most complete information about a planet system ever obtained. For instance, the instruments will investigate the rings at UV, optical, infrared and microwave wavelengths. We will be able to map the chemical makeup and the size distribution of ring material. Some cameras will return images of the rings at resolutions better than a few hundred meters/pixel. It will be essential to observe possible changes at high resolution over a period of 25 yr between the Voyager and Cassini missions and therefore to select peculiar features to be repeatedly observed during the 4 yr of the mission. Finally, one hopes that the orbiter will remove many of the uncertainties currently besetting the problem of ring origin.

Saturn: Satellites

We now know that SATURN has at least 30 satellites, forming a largely diverse set of bodies (figure 1). They range from the planet-like TITAN, surrounded by a dense atmosphere and half the Earth's size, to small, barren objects, of irregular shapes (table 1). The surfaces of the latter objects are all believed to be covered with some type of frozen volatile, primarily water ice, but also carbon dioxide, methane products, ammonia and other volatiles. The surface of Titan remains hidden underneath thick clouds. At some 1.5 billion kilometers from the Sun, nights are terrible on the surfaces of Saturn's companions: −220 ºC. However, during daytime, also, the thermometer never shows more than −170 ºC.

The first of the Saturnian moons, Titan, which is also the biggest satellite after Jupiter's Ganymede, was discovered in 1655 by Christiaan Huygens. Later on, Cassini discovered the next four largest satellites of Saturn: Rhea, Iapetus, Dione and Tethys. The family grew as Earth-based telescopes acquired more resolving power and the Voyager missions visited the system (figure 1). The eighteenth, Pan, was discovered nearly 10 years after the Voyager fly-bys, embedded in the A ring of the giant planet (see SATURN: RINGS). Saturn's ring plane crossings—that is, when the rings move to an edge-on orientation as viewed from the Earth and therefore have their bright light dimmed by satellite eclipses—represent an ideal configuration for discovering new satellites. The recent discovery, in 2001, of twelve new moons of Saturn brings the planet's total to 30: the most in the Solar System. The new moons vary between about 6 and 30 km in diameter, and are moving in irregular, tilted orbits. They fall into several clusters, leading Brett Gladman, of the Observatoire de la Cote d'Azur, Nice, France, and colleagues to conclude that they are the remnants of larger satellites that have been fragmented by collisions. The moons probably began life as wandering bodies that were captured by Saturn's gravity. Gladman and colleagues found the moons by scanning Saturn with sophisticated electronic detectors mounted on medium-sized, ground-based telescopes.

At the beginning of the 20th century, it was recognized that Titan was a special body in our Solar System, the only satellite known to possess a significant atmosphere, which was soon demonstrated to host an active organic chemistry similar, in some aspects, to that found on Earth.

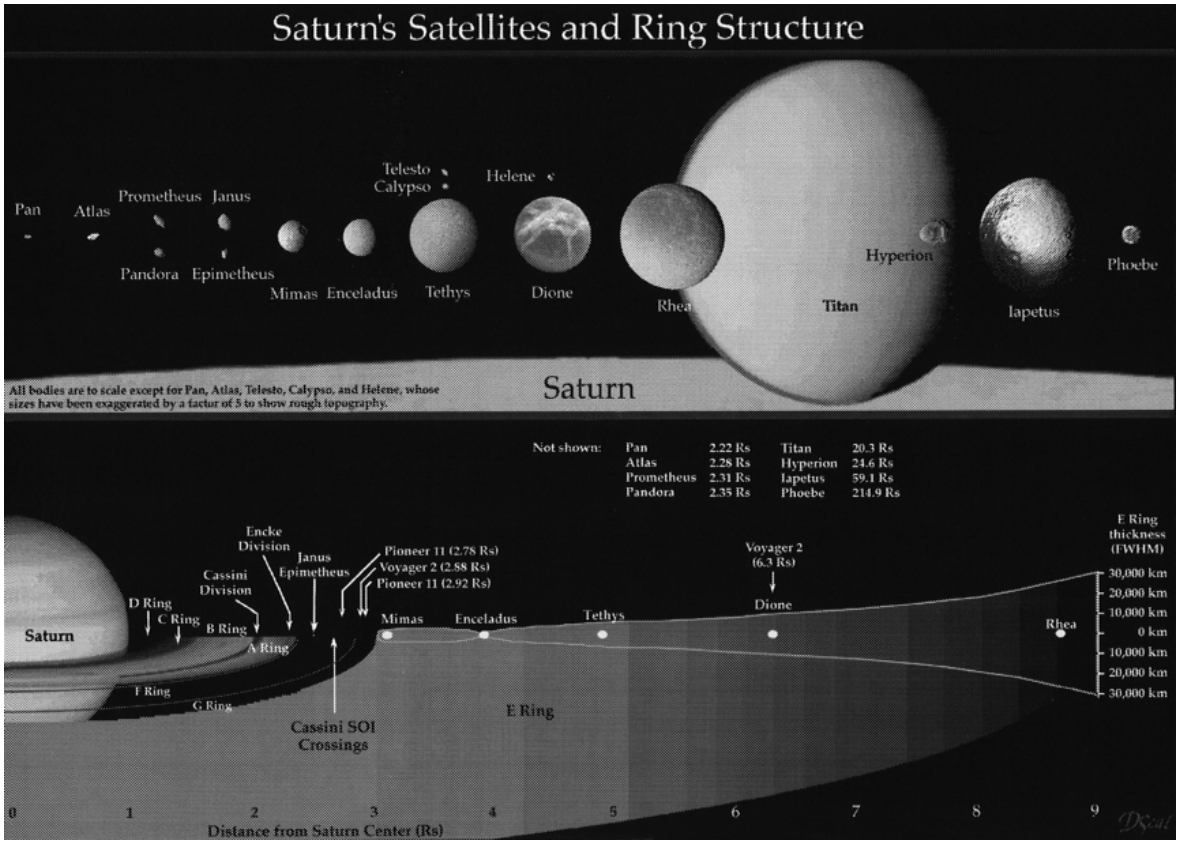

Figure 1. Saturn's satellites are a diverse set of objects, ranging from Titan, a planet-size moon with a dense atmosphere, to Hyperion, a small and dark, irregularly shaped icy body. Some of the satellites are embedded within the ring system.

Phoebe, 1898	16.5	12 952 000	550.40	–	220

Formation and evolution

Our solar system is believed to have formed from the condensation of a primordial cloud of gas and dust about 4.5 billion yr ago (see SOLAR SYSTEM: FORMATION). The outer regions of the protosolar nebula, where the giant planets and their satellites formed, were colder than the inner ones. As a consequence, volatile material, gases with low condensation temperatures, prevailed there and they became the building blocks of the outer bodies. Such materials include methane, ammonia (and their hydrated forms), water ice and ice silicate mixtures. The giant planets and their satellites accreted these components into successively larger lumps of matter, forming the planetesimals. The planets accreted enough mass to maintain large atmospheres and became the gas balls we know today. Their satellites, for the most part, were small blocks of mass, characterized by low density and therefore unable (with the exception of Titan) to hold onto a significant amount of gas to form an atmosphere against thermal escape. The surfaces of these smaller bodies were 'contaminated' by two sorts of carbon- and hydrocarbon-rich material: the C type and the D type respectively.

Following their formation, a long period of heating awaited the newly accreted satellites. The heating was due to the release of the gravitational potential energy and of the mechanical energy produced during the heavy bombardment of their surfaces by remaining debris. The Voyager images also showed that the bright region of IAPETUS (and especially the North Pole) is heavily cratered, as in the cases of Mercury, CALLISTO or the Moon. HYPERION is similar to Iapetus in terms of surface cratering. MIMAS and TETHYS have impact craters (named Herschel and Odysseus), caused by bodies that must have been rather large. Hyperion is believed to have disrupted in the past (as a result of an important impact?) and its debris may have fallen on Titan, which is in a 4:3 resonance with Hyperion. Tidal and resonant interactions among the satellites and among the satellites and Saturn are another source of frictional energy causing heating of the satellites.

Chemical fractionation is possible on most of the larger satellites of Saturn, which may have undergone periods of melting and active geology within a billion years of their formation, before becoming quiescent. ENCELADUS may still be geologically active.

Physical and dynamic characteristics

Most planetary satellites present the same hemisphere toward their primary as a result of tidal evolution. They are in synchronous rotation with the planet. Of Saturn's satellites, only two, Hyperion and Phoebe, are known to exhibit asynchronous rotation.

The Saturnian satellites other than Titan (the largest and most massive of Saturn's satellites, boasting 0.02% of the planet's mass) are too small to retain much of an atmosphere. When GERARD KUIPER, of Chicago

University, discovered in 1944 spectral signatures in the Titan spectrum at wavelengths longer than 0.6 μm, among which he identified two absorption bands of methane at 6190 Å and 7250 Å, he also searched for a similar behavior in the spectra of other Saturnian satellites. In data he had obtained in 1952, he found—by contrast—differences between Titan and the other satellites in the intensity observed in the ultraviolet and visible continuum. These differences, due to the presence of an atmosphere around Titan, hinted at the lack of such an adornment on the smaller satellites of Saturn. As a consequence, astronomers expected them to be simply icy, geologically dead bodies. However, the era of space exploration had some surprises in store for the scientists.

High-resolution photometry and spectroscopy have shown that the main constituent on the surface of the brightest among Saturn's satellites is water ice. Their densities (ranging from 1.0 to 1.9) are such that ice must be a major constituent of the interior, also. The most probable structure for each of them (and Titan too) is a rocky center surrounded by a thick shell of ice. Taking typical densities for rock and ice, and knowing the size of the satellite and its mass, a model for the relative sizes of the rocky core and icy mantle can be worked out. In the case of smaller satellites, such as Janus and Epimetheus, the densities are of the order of 0.65.

Of course, the ice and the rock will not be pure water or silicate but may contain many impurities. The icy surfaces are obviously contaminated by materials of various colors and these can be studied using spectroscopy. Contrary to what was previously believed, the Voyager and Galileo spacecraft revealed in 1980 and 1995–1998 a wide range of geological processes on the moons of the outer planets and showed that several of the larger Kronian satellites may have undergone melting of their mantles and subsequent differentiation and resurfacing of the liquid ice or ice silicate mud. Flows of these liquid components are similar to the lava flows witnessed on Earth and the Moon, owing to the melting of silicate rock mixtures. The ridged and grooved terrain found on Enceladus and Tethys may be the result of tectonic activities occurring throughout the solar system. Explosive volcanic eruptions may be occurring on Enceladus, as on Earth.

In the young solar system, meteoritic bombardment was intense and frequent causing the surfaces of icy satellites (among others) to be heavily cratered. Nowadays the bombardment continues but at a significantly lower rate. Knowing something about the flux of impacting material and by enumerating the number of CRATERS on a solid surface, geologists can recover information on the origin and epoch of formation of ground portions. Impacts have several consequences: they pulverize the rock and the icy components of a surface, forming a fine material that covers it, the REGOLITH; they tend to excavate and expose fresh material on the surface; they also cause the vaporization and escape into space of volatiles, leaving behind on the ground a deposit of opaque and dark material. As a consequence, the larger satellites of Saturn, like those of Jupiter (see JUPITER: SATELLITES), have a brighter 'leading' than 'trailing' hemisphere (a leading side is the hemisphere seen from the Earth when the satellite moves toward our planet; the trailing side is the opposite in the direction of orbital motion). This is the case for Hyperion and Titan, for instance, but not for Iapetus, as will be discussed in the following section. The hemispheric asymmetry is believed to be due to more meteoritic encounters occurring on the leading side. The fact that well-formed craters, similar to those observed in the inner solar system bodies, are also observed on the Galilean and Kronian satellites today, suggests that the surface ice is strong enough to sustain intense impacts, perhaps because it is mixed with silicate contaminants or other impurities. The low temperatures and the small surface gravity in these cases prevent viscous relaxation from eradicating the impact features. Mimas is thus covered with high-rimmed, bowl-shaped craters, Herschel being the most prominent one (130 km large).

Individual properties

With a diameter of more than 500 km, the six larger satellites of Saturn are Titan (5150 km, half our own Earth), followed by RHEA and Iapetus (less than a third of Titan's size), DIONE and Tethys (with close to 1000 km diameter) and Enceladus, the smallest of the mid-size satellites (table 1; figure 2). Hyperion, Phoebe (farthest from Saturn), Janus, Epimetheus, Mimas and Prometheus afford diameters of more than 100 km, being sizable objects. The latter four are found close to their primary and are therefore difficult to observe from the ground because of the planet's scattered light. Most among these and the even smaller icy satellites (such as Pan, Atlas, Pandora, Telesto, Calypso and Helene), were not discovered before the 1980s. Most of what is presently known about the Saturnian system is due to the extraordinary exploration of the two Voyager missions, which encountered Saturn, its rings and satellites in 1980 and 1981.

The satellites have low densities and high ALBEDOS. They were therefore expected to be largely composed of water ice, probably combined with ammonia and other volatiles. Spectroscopic measurements performed on the medium-sized Saturnian satellites confirm this hypothesis by showing the spectral signatures of ice. Even Titan's surface, eternally hidden by a thick cloud deck and only recently explored by imaging and spectroscopy in the near-infrared, is believed to be covered with some sort of 'dirty' water ice. Other areas of the satellite's surface are expected to host a variety of landscapes, ranging from hydrocarbon lakes to ice-covered mountains.

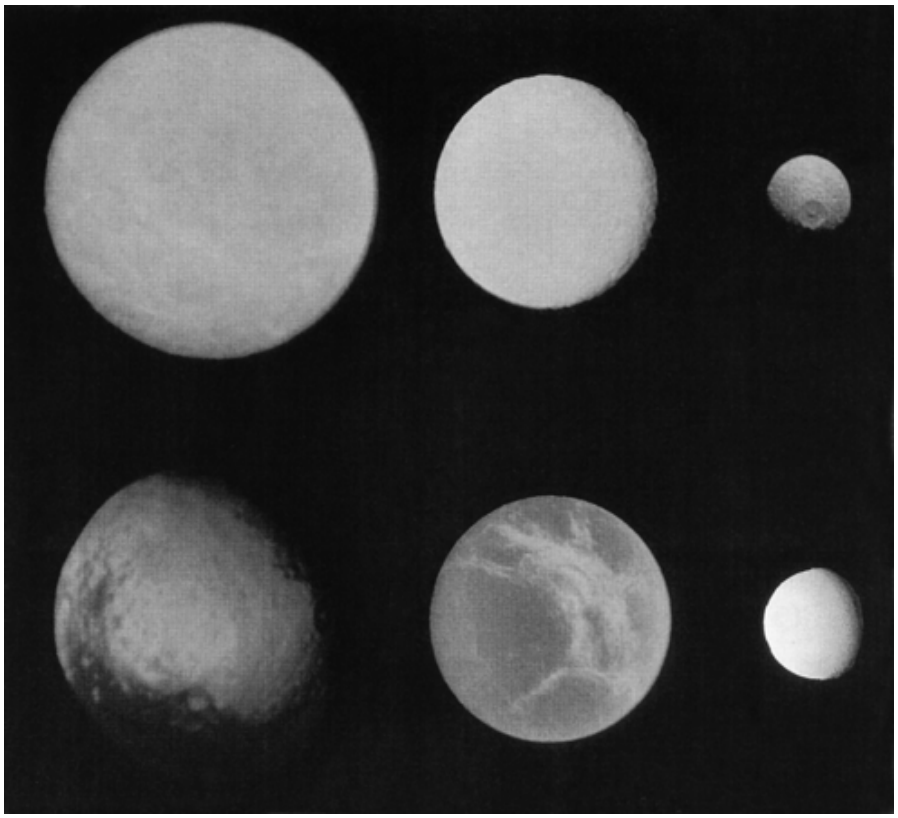

Figure 2. The six largest icy Kronian satellites are all unique worlds; from top left and clockwise, Rhea, Tethys, Mimas, Enceladus, Dione and Iapetus.

The larger satellites

After the planet-sized Titan, four large and four medium-sized satellites share the system's mass: Rhea, Iapetus, Dione and Tethys are kilometer-sized objects, while Enceladus, Mimas, Hyperion and Phoebe are less than half that size.

Iapetus is not like the other Kronian satellites in that it is the only large satellite of Saturn in a highly inclined orbit and—for no obvious reason—its two faces are radically different, one bright and the other very dark (figure 3). The surface albedo on the trailing hemisphere varies from 0.4–0.5, values typical for ice-covered objects, to as low as 0.02 in the central parts of the leading hemisphere. Already in 1672, when CASSINI discovered Iapetus, it was noticeable that, at one point on its orbit around Saturn, the satellite seemed quite bright, whereas on the opposite side of the orbit it almost disappeared. Cassini then correctly deduced that this was ample indication for a marked difference between the moon's two hemispheres, with one of them (the trailing hemisphere, in other words the side viewed from the Earth when the satellite moves away from us) bearing highly reflective material, while the other (the leading hemisphere, or the side facing the Earth when the satellite moves toward us) was of a darker nature.

Images of Iapetus obtained by Voyager confirm these observations and show that the bright region, reflecting about 50% of the incident radiation, is typical of heavily cratered icy surfaces. The other side is centered on the direction of motion around Saturn and is coated with a redder material. This gives a symmetrical distribution about the apex of the orbital motion. In the craters found near 200ºE longitude, the shape and orientation of the dark deposits suggest that they cover bright terrain and that they are, in consequence, more recent. The mean density of the satellite is 1.03 g cm^{-3}, somewhat less dense than the other icy satellites of Saturn, but still consistent with models predicting water ice as the main component of these bodies (although this may be indicative of a higher fraction of ice in its interior). The dark material on the surface must then have been deposited in a very thick layer if it can cover large quantities of ice.

Because Voyager was unable to map the surface on the whole leading hemisphere, the nature and origin of the dark material on Iapetus remain a mystery. The observed symmetry with respect to the direction of the orbital motion of the satellite strongly argues in favor of an external control, or even perhaps an external origin for this material. Studies of its composition, based on ground-based low-resolution observations performed at

Dirac House, Temple Back, Bristol, BS1 6BE, UK

the infrared telescope facilities, the United Kingdom Infrared Telescope and the University of Hawaii telescope from 1981 to 1983, show that it is very red in the visible and near-infrared. A fit of the Iapetus spectrum was obtained at first by using a mixture of polymers (10%) and hydrated silicates (90%), simulated in the laboratory. A more recent study, however, achieves a better agreement with a mixture of HCN polymers, organic residuals and water ice.

The mechanisms suggested for the production of this dark material are (a) a layer of eroded dust from the surface of Phoebe (the dark outermost Saturnian satellite, characterized by a highly inclined, retrograde orbit and with a surface albedo similar to but a little less red than that of Iapetus) pulled inwards and (b) a leading hemisphere surface modified by impacts from Phoebe material, leading to a low-albedo material concentration on that side of the surface; in the latter case, the dark material would be of endogenic origin, but controlled by exogenic impacts. A recent study of some UV Voyager archived images, in accordance with these models, suggests impacts of exogenic material from round-shaped Phoebe on the surface of Iapetus, leading to ice evaporation and leaving a dark and red deposit on the crater floors. This deposit would be a mixture of Phoebe material and a pre-existent non-volatile constituent, uncovered by the impacts, similar to the D-type material found in the asteroids of this type, as well as on Hyperion (an example would be methane erupting from the interior and subsequently being darkened by ultraviolet radiation). The major problem with the exogenic models is that the dark material on Iapetus is generally 'redder' than that found on Phoebe. However, it is conceivable that dark particles ejected from Phoebe may have undergone chemical changes that rendered them redder. Smaller than Hyperion, Phoebe's eccentric orbit suggests it may be a captured object. With a rotational period of about 9 h, Phoebe is the only Saturnian satellite to exhibit a simple, asynchronous rotation.

Hyperion is a special satellite because of the complex aspect of its chaotic rotation and its irregular shape. Although its global composition is uncertain, we know that water ice is present on the surface. Its spectrum in the visible range and in the near-infrared is compatible with that of Titan, showing a brighter leading and a darker trailing hemisphere. Hyperion is in 4:3 resonance with Titan and it has been suggested that Hyperion material was deposited in the past on Titan. Hyperion's albedo is rather low (0.21 in the visible), lower than all satellite albedos but for the ones of Phoebe and Iapetus. Its red color and low albedo value suggest the presence of an additional component (besides water ice) on the surface of Hyperion. A partial coverage by Phoebe-originating material has been suggested in this case also, as on Iapetus. One cannot exclude, however, the possibility of the existence of a certain intrinsic dark material which would have found its way to the surface through 'pockets' located in the regolith.

Because of the differences between the albedo values of Iapetus and Hyperion, different mixtures of surface material are required. Dark organic material and hydrated silicates are likely candidates for the composition of the external objects of our solar system and could explain the albedos of both Hyperion and Iapetus. It is worth noting that Hyperion is the satellite closest to Saturn after Iapetus and, consequently, it is quite conceivable because of this proximity that its surface may be covered by a similar material, which, however, was not deposited in the case of Hyperion preferentially on one of the hemispheres, owing to its chaotic rotation.

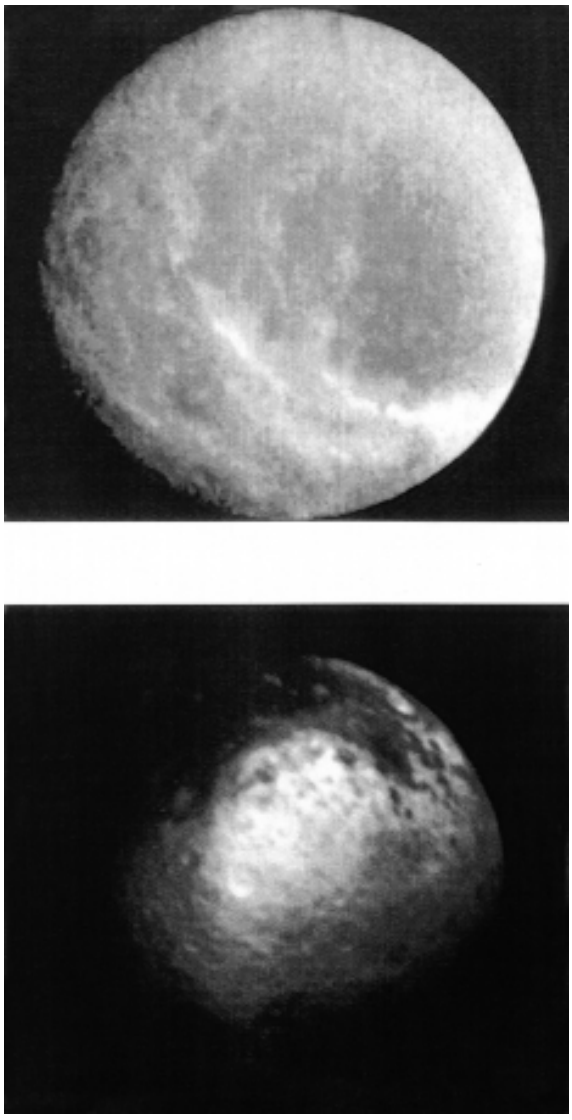

Figure 3. Rhea (upper half), the second largest satellite of Saturn, after Titan, shows an array of bright streaks, whereas Iapetus (bottom half) exhibits both bright and dark terrains on this Voyager 2 image.

Thus, among the medium-sized icy satellites of Saturn, Hyperion and Iapetus are historical mysteries presenting a pronounced hemispheric asymmetry, also observed on Titan. The observational data that we possess today have not provided yet a valid explanation as to the composition of the surface of these satellites. The nature of the dark component observed is not yet discovered.

Rhea is the second most massive satellite of Saturn (figure 3), but still possesses less than 2% of Titan's mass. The surface of Rhea bears distinct signs of multiple impacts and is heavily cratered. One hemisphere shows bright wispy streaks that may have been caused by ejecta from impacts or perhaps have been caused by the condensation of volatiles leaking from the interior as a sign of internal activity. Parts of the ground are covered with large craters while other regions lack them. The larger craters are probably the signatures of early bombardment, while the smaller ones may have been more prevalent during a later episode of collisions. In many respects Rhea looks very much like the MOON or MERCURY, although the morphology of individual craters is somewhat different.

Dione appears to be quite similar to Rhea on the images, showing a wide diversity of morphology (figure 4). It also shows parts in which craters seem to be too few in number, as though many have been obliterated or covered up, indicating that several periods of resurfacing have occurred during the first billion years of its existence. It therefore appears that, although small, these bodies afforded, nevertheless, in some distant past significant internal activity. This could be the case if the relatively high densities have provided added radiogenic heat from siliceous material to spur this activity. The leading hemisphere of Dione is about 25% brighter than the other, as a result of more intense meteoritic bombardment on this side.

Icy Tethys is heavily cratered, (figure 4), similarly to Mimas, one of Saturn's inner satellites. Mimas' remarkable crater (figure 5), Herschel, is about the same size as Tethys' Odysseus (400 km in diameter, ~40% of the diameter of the satellite, the largest crater in the Saturnian system). This outstanding topographic feature is accompanied by a huge trench formation, the Ithaca (Odysseus' home country) Chasma, similar in appearance to the grooves on Enceladus. Viscous relaxation and flow in the craters of Tethys under the influence of its strong gravitational field give them an aspect flatter than for Mimas or the Moon. Regions where craters are fewer give evidence for several episodes of resurfacing in contrast to Mimas, where surface gravity is not sufficient to have caused viscous relaxation and craters tend to be high-rimmed, bowl-shaped pits.

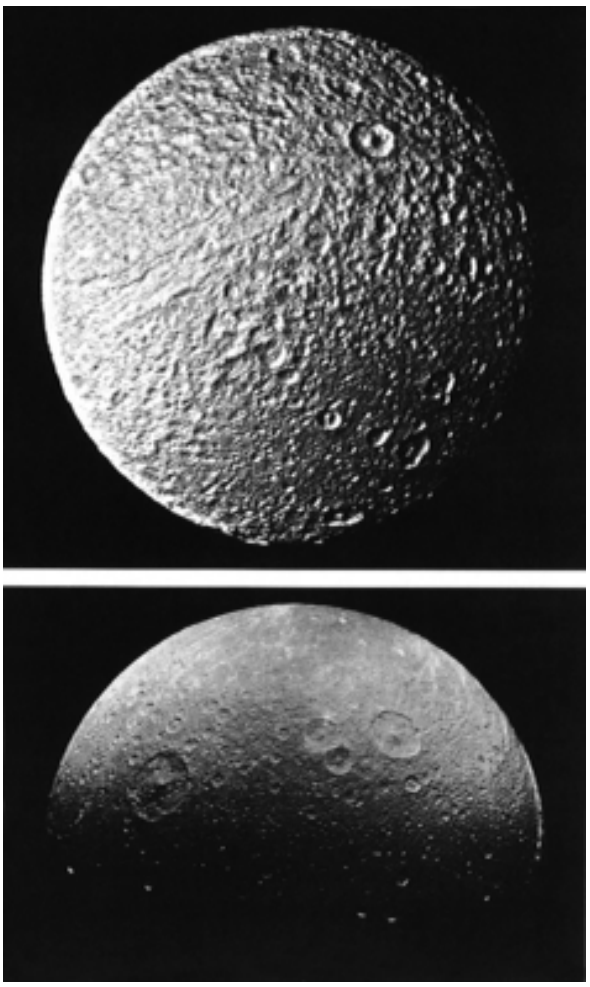

Figure 4. The surface of Tethys (upper half) shows many impressive craters, the most prominent of which is Odysseus (400 km, the largest impact structure in the Saturnian system) and Telemachus, as well as the Ithaca Chasma, a groove-like trench formation. Dione's surface (lower half) is also heavily cratered, as shown on this Voyager 1 image, with bright wispy streaks visible on the limb.

Enceladus may well be one of the most interesting and beautiful examples among the primitive, airless worlds accompanying Saturn (figure 5). Extremely close to its planet, at a distance of 238 000 km, Saturn's apparent diameter (25º) in Enceladus' sky is 50 times larger than that of the Moon seen from the Earth. Part of its surface was detected by Voyager and seemed entirely covered with vast plains of ice, an ice so pure and bright that it reflects almost all the visible radiation incident on it (by comparison, our Moon reflects only 11% of the light it receives). Enceladus shines bright: the only plausible composition for this part of its surface is pure water ice or some other very bright volatile. Here and there, on Enceladus, dark spots testify to the presence of craters, but not very many. In fact, this lack of impact craters on half of Enceladus' surface points to a relatively small age, less than a billion years, and subjection in the

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

recent geological past to extensive resurfacing, while some form of ice volcanism may still be occurring. This phenomenon may well be responsible for the formation of the E ring around Saturn, by providing the source of particles. The other half of the surface, as seen by Voyager 2, was a great relief for geologists because it appeared heavily cratered, and is therefore compatible with an age of 4 billion yr. The complex nature of Enceladus' surface is a delight to astronomers.

The smaller satellites

Ten of the Saturnian satellites are decent-sized objects. However, the system also has a number of unique small satellites under or around 200 km in diameter (figure 6). These are distinguished in basically three classes of objects: the shepherding satellites, Atlas, Pandora and Prometheus, believed to play a key role in defining the edges of Saturn's A and F rings; the co-orbital satellites, Janus and Epimetheus, move in almost identical orbits at about 2½ Saturn radii; finally the Lagrangian satellites, Calypso, Helene and Telesto, are so called because they orbit in the Lagrangian points of larger satellites, Dione and Tethys. Lagrangian points lie about 60º in front of and behind the larger body, and correspond to locations within an object's orbit in which a less massive body can move in an identical, stable orbit. No other satellites in the solar system are Lagrangians. The only other similar example we have is of the Trojan asteroids orbiting in two of the Lagrangian points of Jupiter.

Of the shepherds, Atlas lies several hundred kilometers from the outer edge of the A ring. The other two orbit on either side of the narrow F ring, constraining its width and causing its kinky appearance.

Janus and Prometheus, discovered in 1966 and 1978 respectively, may once have been part of a larger body that disintegrated following a major collision. Every 4 yr, the inner satellite (which orbits slightly faster than the outer one) overtakes its companion. Instead of colliding, the satellites simply exchange orbits. The 4 yr cycle then starts all over again.

Pan was discovered in 1990 in Voyager 2 images dating back to 1981. The small object lies hidden within the A ring and helps to keep the Encke division clear of particles.

Future investigations

The two Voyager spacecraft provided the first detailed reconnaissance of the Saturnian system, with Titan as one of the major poles of attraction. It seems, nevertheless, that this precious data set did but whet our appetite for our exploration of this world. Titan has become in recent years one of the main goals for the CASSINI/HUYGENS MISSION to the Saturnian system, a joint ESA–NASA mission, launched in October 1997 and which will reach its target in 2004.

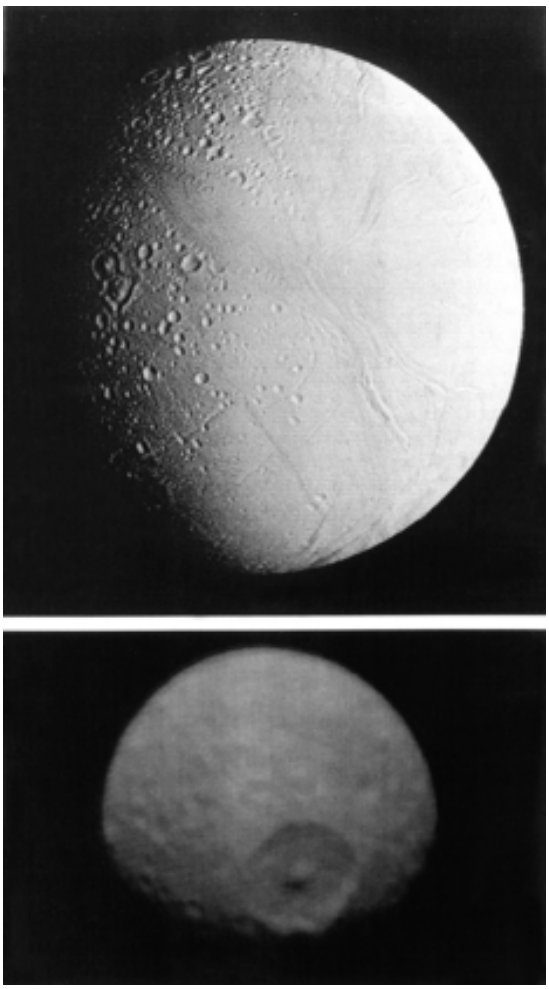

Figure 5. Saturn's icy moon Enceladus (upper half), shows a bright surface with evidence of numerous resurfacing episodes in the past. Mimas (lower half), is a small object with crater Herschel (about 130 km in diameter), nearly centered on the leading hemisphere.

Perhaps only then will some of the remaining questions regarding Titan and the other Saturnian satellites find an answer. Succinct examples are given below.

- Are there more satellites around Saturn than those known today? They could be, for instance, embedded in the ring system, and hence difficult to detect. High-resolution imaging by the Cassini Imaging Science Subsystem (ISS) will help discover even kilometer-sized objects.
- What is the detailed morphology and the exact composition of the surfaces of the satellites? For example, what is the distribution of dark material on Iapetus' craters and what does that tell us about the origin of this material? Besides ISS imaging, the three Cassini spectrometers (CIRS, UVIS and

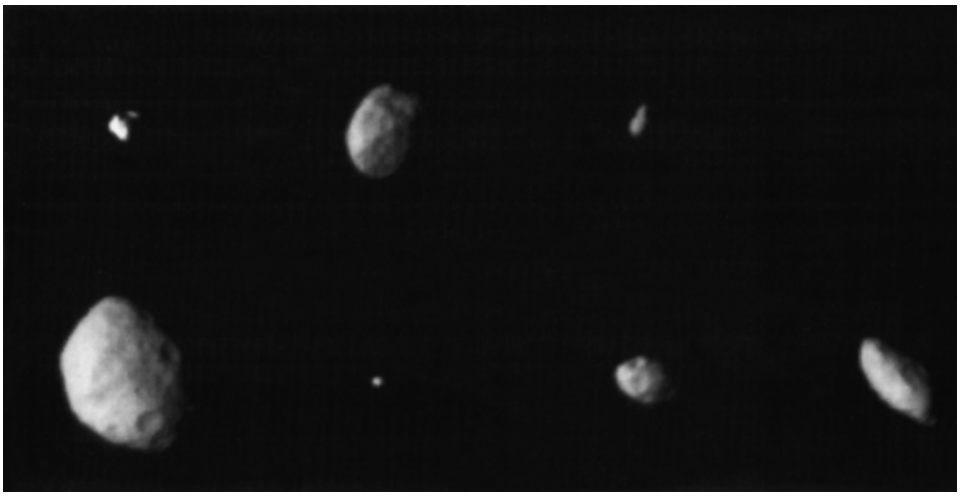

Figure 6. Seven of Saturn's small inner satellites. Clockwise from top left: Helene, Epimetheus, Calypso, Prometheus, Pandora, Telesto and Janus.

VIMS) will probe the satellites' surfaces in high-resolution mode (capable of distinguishing tens of meters on the ground) and thus allow us to correlate geophysical units with specific compositions.

- What is the connection between the rings, the dust (which, along with the icy particles, will be measured in detail by the Cosmic Dust Analyzer—CDA—on board Cassini) and some of the satellites in the Saturnian system and how does this help us understand its formation and evolution? For instance, is Enceladus the source of the E ring?
- Do any of the other Saturnian satellites, besides Titan, possess even a thin, tenuous atmosphere and what is its composition? The Cassini spectrometers will here again enable us to detect such atmospheres and their interaction with Saturn's magnetosphere (as in the case of Titan) will be studied by the Dual Technique Magnetometer (MAG), the Magnetospheric Imaging Instrument (MIMI), and the Cassini Plasma Spectrometer (CAPS). The Ion and Neutral Mass Spectrometer (INMS), the CDA and the Radio and Plasma Wave Science Instrument (RPWS) on board Cassini will on the other hand study the composition, size and mass of material eroded or expelled from the satellites' surfaces.

In the 4 yr mission of Cassini, numerous close fly-bys of the Saturnian satellites will allow us to determine their characteristics with precision and tie these precise measurements to the origins, evolution and fate of the Kronian system and furthermore to that of the solar system as a whole.

Scaliger, Joseph (1540–1609)

French mathematician who, in 1582, founded the system of the Julian day, a continuous reckoning of time which starts at midday GMT on 1 January 4713 BC. The system has the advantage that it is able to set aside issues of leap years, the different lengths of months, 'lost' days at changes of calendars etc. The label 'Julian' commemorates Scaliger's father Julius.

Schall von Bell, Johann Adam (1592–1666)

Astronomer, born in Cologne, Germany, became a Jesuit and studied astronomy in Rome. He was one of numerous Jesuit missionaries sent to China, and was the first European ever to be a member of the court bureaucracy in Peking, becoming head of the Imperial Board of Astronomy, and adviser to the young emperor Shun-chih (ruled 1644–61). He produced a large six-part cosmological map, accompanied by pictures of astronomical instruments, he translated astronomical books and he reformed the Chinese calendar. He was falsely implicated in the death of the emperor, and escaped execution only through a fortuitous earthquake.

Scheiner, Christoph (1575–1650)

Astronomer, born in Wald, near Mindelheim in Swabia (southwest Germany), became a Jesuit and professor of mathematics at the university at Ingolstadt. He made instruments, including sundials and a pantograph. On learning about GALILEO's discoveries, he obtained his own telescopes, with which he observed the Sun, and in 1611 independently discovered sunspots for himself. His publication on the subject started from the Aristotelian concept of the perfection of the Sun, so he proposed that sunspots represented transits of satellites of the Sun. He came into conflict with Galileo, who argued that sunspots are on the surface of the Sun, because they change their shapes, and they originate and perish on the solar disk. Scheiner at first persisted stubbornly against the evidence. In Rome he published *Rosa Ursina* (1630), a work on sunspots that was required reading for a century. His theories having been repeatedly dismissed by Galileo, Scheiner attacked him in the book, although by then he had actually accepted many of Galileo's opinions. Shortly after the appearance of *Rosa Ursina*, sunspot activity decreased drastically (the MAUNDER minimum, 1645–1710), and Schiener's work could not be verified or superseded. Scheiner retired to Vienna and Neisse, building a Jesuit college and writing a massive refutation of the Copernican theory (*Introductory Treatise in Favour of a Moving Sun and a Stable Earth against Galileo Galilei*), which, posthumously published, had no influence whatsoever.

Schiaparelli, Giovanni Virginio (1835–1910)

Astronomer, born in Savigliano, Italy, studied in Berlin and at Pulkova, Russia, and became director of Brera Observatory, Milan. He wrote authoritative accounts of the early astronomy of many cultures. He observed comets, inferring from their tails that there was a repulsive force from the Sun (solar wind and radiation pressure). He explained the regular meteor showers as the result of the dissolution of comets and proved it for the Perseids by calculating orbital effects on the Perseid shower. From his observations, he mapped Mars, naming martian 'seas' and 'continents' and connecting features with linear features which he called 'channels' or, in Italian, *canali*. The implication that these features, mistranslated 'canals', were artificial water-distribution systems, stimulated PERCIVAL LOWELL to a sensational search for life on Mars.

Schickard [Schickhardt], Wilhelm (1592–1635)

Born in Herrenberg, Württemberg, Germany, became professor of astronomy in T'bingen. He corresponded with KEPLER, was one of the first to teach Kepler's discoveries, and, on the basis of his experience in making maps and other devices, proposed to Kepler the development of an analog computer to calculate planetary positions. He invented the first calculating machine, a 'hand planetarium' (like an orrery) and a machine for Hebrew grammar. He died of the plague.

Schlesinger, Frank (1871–1943)

Astronomer, born in New York City, became director of the University of Pittsburgh's Allegheny Observatory and the Yale University Observatory. He developed a method to observe stellar parallaxes photographically, and compiled a catalog of 4000 stellar distances. He compiled data to produce the first and second editions of an influential and practical *Catalog of Bright Stars*.

Schmidt Telescope

A type of telescope, invented by the Estonian optician Bernhard Schmidt (1879–1935), that is used to photograph large areas of the sky. Because, in its original design, it was useable only for photography, the instrument is also known as the Schmidt camera. The Schmidt uses a concave spherical mirror as its light collector and corrects for the optical defect, known as spherical aberration, that is introduced by a mirror of this shape, by means of a specially shaped thin lens, or corrector plate, which is located at the front end of the telescope tube. An instrument such as this, which uses both lenses and mirrors to collect light, is called a catadioptric instrument

By contrast with a conventional telescope, where the sharply focused field of view may be only a few arc minutes or, at best, a few tens of arc minutes, the field of view of a Schmidt telescope may be six to ten degrees across. Its wide field of view makes it eminently suitable for surveying large areas of sky. A disadvantage of the system is that the surface of sharp focus (the focal 'plane') is curved rather than flat. This problem is overcome by bending the photographic plate, film, or detector to match the shape of the surface of sharp focus.

Because the corrector plate has to be situated at the center of curvature of the primary mirror, its distance from the mirror is twice as great as the focal length of that mirror. Consequently, the tube of a Schmidt telescope is at least twice as long as the focal length of its primary mirror. Because the correcting lens causes a degree of divergence in the incoming light rays, the diameter of the primary mirror has to be greater than that of the corrector plate. The maximum size of a Schmidt camera is limited by the practical problems associated with supporting the thin lens (which can be supported only round its edges). The largest Schmidt telescopes in the world, one located at Mount Palomar, California, and the other at Siding Spring, Australia, each have corrector lenses with diameters of 1.2 m.

Schmidt, Bernhard Voldemar (1879–1935)

Optical designer, born on the island of Naissar, off the coast of Tallin, Estonia. In spite of an accident at the age of 15, in which he lost his right hand and forearm, he successfully made fine optics for amateur astronomers. He started an optical workshop in Mittweida, Germany, and his reputation spread. He worked at the observatory in Bergedorf (near Hamburg) as an optician and made observations of Jupiter, Saturn, the Moon and eclipses. During the eclipse expedition of 1929, Schmidt discussed a camera for wide-angle sky photography with WALTER BAADE, and invented the *Schmidt telescope* or *Schmidt camera*. The camera has a spherical mirror and an aspheric corrector plate of half the mirror's diameter. Its optics is almost identical when viewed from over a wide angle and the pictures that it takes are therefore almost uniform in quality. The focal plane is curved, but nevertheless, in the largest Schmidt telescopes (e.g. on Mount Palomar and in Coonabarabran) which have corrector plates of 48 in diameter, 14 in photographic plates can be exposed. These telescopes have been used to survey the entire sky for stars, galaxies and nebulae of different kinds.

Schmidt, Maarten (1929–)

Astronomer, born in Groningen, Netherlands, worked on galactic dynamics and the mass distribution of the Galaxy with JAN OORT at Leiden and went to CalTech, and became director of the Hale Observatory. In 1963 he observed 3C273, a radio source which had been identified by Cyril Hazard with a blue star by using the edge of the Moon as a scanning device when the Moon occulted the source. With a 200 in telescope picture, he discovered that there was a jet protruding from 'star'. He obtained a spectrum, which like 3C48 studied by ALLAN SANDAGE, showed emission lines at unusual positions. Schmidt's breakthrough was to recognize that the object exhibited ordinary hydrogen lines, but at a redshift far greater than those observed in stars. The distance that was implied meant that the power output of the object was very large, and connected with the jet mechanism. This was the first completed discovery of a quasar. Schmidt went on to investigate the distribution of quasars, discovering that they were much more abundant when the universe was young.

Schmidt–Cassegrain Telescope

A form of telescope that combines some of the features of the Schmidt and the Cassegrain systems. The principal optical components of the Schmidt–Cassegrain are a concave primary mirror, a thin corrector lens located close to the focus of the primary, and a convex secondary (which is often attached directly to the inside of the corrector lens), which reflects light through a central hole in the primary to a focus. The curved secondary changes the angle at which light rays from the primary mirror are converging and, as with the conventional Cassegrain, increases the effective focal length of the instrument while keeping down its overall length. The corrector lens gives a wider field of sharp focus than that of the conventional Cassegrain. The Schmidt–Cassegrain is an example of a catadioptric system, one that uses both lenses and mirrors to collect light.

Schröter Effect

A phenomenon in which the observed and predicted phases of Venus do not coincide. It applies in particular to the predicted and observed times of dichotomy (half-phase), at which the terminator—the boundary between the illuminated and unilluminated portions of Venus's disk—should be a straight line. At eastern elongation, when the planet is visible in the evening sky, dichotomy usually comes a day or two earlier than it theoretically should, while at western elongation, when Venus is visible before sunrise, dichotomy tends to occur a day or two later. The effect is named after Johann Schröter, who first described it in 1793. There is no satisfactory explanation for the Schröter effect. It may be purely subjective, or it may have a physical cause, perhaps the scattering of twilight in Venus's thinner upper atmosphere.

Schröter, Johann Hieronymous (1745–1816)

Magistrate of Lilienthal near Bremen, Germany, assiduous mapper of Mars, although he believed that all martian markings were duststorms. The *Schröter effect* in Venus is the gap of a day or two between the time of the geometrical dichotomy of Venus and the time at which Venus actually appears as a half-circle (an effect of Venus' atmosphere). His assistant K L HARDING discovered Juno, and F W BESSEL began his career at his observatory, which, with his records, his wealth and his position, was lost during the Napoleonic war.

Schramm, David N (1945–97)

Cosmologist, born in St Louis, MO, studied with WILLIAM FOWLER, became professor at the University of Chicago. He was a founder of the subject of 'astro-particle physics', studying the particle-physics properties of the Big Bang at the start of the universe. When only two families of particles were known, Schramm predicted from cosmological considerations that there would be just one more family, a prediction confirmed in 1989 by experiments at particle accelerators in Stanford and Geneva. He worked on the nuclear physics by which light elements (hydrogen, deuterium, helium, lithium, beryllium and boron) were produced in the Big Bang. Schramm was a large man and a champion wrestler. He was killed piloting his own plane.

Schwabe, Samuel Heinrich (1789–1875)

Born in Dessau, trained as a pharmacist. When he sold the family pharmacy he became financially independent and was able to turn to astronomy, erecting an astronomical observatory on top of his house, from which he made observations of the Moon, the Sun and the planets. Schwabe began a search for the planet Vulcan inside Mercury's orbit, hoping to find it amongst the sunspots that he observed and listed. After 17 years he began to suspect a regular variation in sunspot numbers, with a period of about 10 years. His under-sold article 'Solar observations during 1843' was overlooked until ALEXANDER VON HUMBOLDT drew attention to it in *Cosmos*, his encyclopedia of natural science. The 11 year cycle was confirmed by Julius Schmidt, RUDOLF WOLF, EDWARD SABINE, and J von Lamont, in both the sunspot cycle and in the Earth's magnetic field.

Schwarzschild, Karl (1873–1916)

Mathematical physicist, born in Frankfurt am Main, Germany, at first worked on celestial mechanics, including POINCARÉ's theory of rotating bodies, the tidal deformation of moons and LAPLACE's origin of the solar system. He became professor at Göttingen and Potsdam. He wrote on relativity and quantum theory. He early on proposed that space was non-Euclidean, giving a lower limit for the radius of curvature of space as 2500 light years, and in his mature papers gave the first exact solution of EINSTEIN's general gravitational equations about the geometry of space near a point mass. This led to the first relativistic study of black holes. The size of the 'event horizon' within which light cannot escape from a black hole is called the *Schwarzchild radius*. His mathematical formulation of the description of the geometry of space is called the *Schwarzchild metric*. He served in the Army in the First World War, contracting an illness while in Russia from which he died on returning home.

Schwarzschild, Martin (1912–97)

Astrophysicist, born in Potsdam, Germany, the son of KARL SCHWARZSCHILD, left Germany, became professor at Princeton University. Working with John von Neumann, Schwarzschild used the powers of the newly developed electronic digital computers to work on the theory of stellar structure and evolution. He uncovered phenomena in red giant stars, including how they evolve off the main sequence in the Hertzsprung–Russell diagram, how they generate energy in hydrogen shells, the helium flash and the ages of star clusters. He summarized his work in an influential text-book, *Structure and Evolution of the Stars*. In the 1950s and 1960s Schwarzschild pioneered the use of space telescopes for precise imagery of the Sun, planets and stellar systems. Stratoscope I, a 12 in telescope lifted to 80 000 feet altitude by balloon, was the first instrument to obtain sharp photographs of the Sun from above most of the Earth's atmosphere. Stratoscope II, with a 36 in telescope, yielded infrared images and spectra of the outer planets, red giant stars and galactic nuclei.

Scintillation

Rapid fluctuations in the radiation from stars due to its passage through the atmosphere. The more familiar term for the effect on visible light is 'twinkling'. The effect is most marked for a point source of light, such as a star. An extended source (covering a finite area) does not exhibit the effect so appreciably (thus a planet tends to twinkle less obviously than a star). Scintillation is caused by turbulence in layers of the atmosphere (which may have differing temperatures, refractive indices, velocities, etc). Seen from space, stars would not appear to twinkle.

At radio frequencies it is possible to detect scintillation due to the passage of radiation through the solar wind. Analogous to the twinkling of stars, the distortion of radio emissions in the ionosphere occurs at wavelengths longer than about 20 cm (1.5 GHz).

Scorpius

(the Scorpion; abbrev. Sco., gen. Scorpii; area 497 sq. deg.) A southern zodiacal constellation which lies between Ophiuchus and Ara, and culminates at midnight in early June. Its origin dates back to Sumerian times, when it was called Girtab, 'the stinger', but today it is associated with the scorpion that, in Greek mythology, killed Orion the hunter—and the two constellations lie on opposite sides of the sky. Scorpius was originally a larger constellation, which was divided into two by the ancient Greeks, the western part, Chelae (the Claws—of the Scorpion), being renamed Libra by the Romans in the first century BC (*see* Libra). The brightest stars of Scorpius were cataloged by Ptolemy (*c.* AD 100–175) in the *Almagest*. (An alternative form of the name for the constellation, Scorpio, is used by astrologers.)

A conspicuous constellation and one of the few that even remotely resembles the object after which it was named, Scorpius is easily recognized by α Scorpii (Antares), a red giant irregular variable (range 0.9–1.2), which marks the scorpion's heart, and an arc of second to fourth magnitude stars, ε, μ^1/μ^2, ζ, η, θ, ι^1, κ, λ and υ Scorpii, marking its tail and sting.

α Scorpii is also a close binary, it having a bluish-white (B2.5) companion, magnitude 5.4, separation 2.9″, which appears pale green in contrast with its red (M1) primary. Other bright stars include λ Scorpii (Shaula), magnitude 1.6, θ Scorpii (Girtab or Sargas), magnitude 1.9, δ Scorpii (Dschubba), magnitude 2.3, ε Scorpii, also magnitude 2.3, and κ Scorpii, magnitude 2.4. There are 14 other stars of magnitude 4.0 or brighter, including β Scorpii (Acrab or Graffias), an optical double consisting of two bluish-white (B0.5 and B2) components, magnitudes 2.6 and 4.9, separation 13.7″, the former of which has two companions, magnitudes 5.9 and 4.2, separation 0.5″ and 0.001″ (orbital period 6.83 days), and the latter a companion of magnitude 7.6, separation 0.1″. Another interesting multiple star is ν Scorpii, which has two bluish-white (B2 and B8) components, magnitudes 4.1 and 6.8, separation 41″, each of which has a close companion, magnitudes 6.2 and 7.5, separation 1.3″ and 2.3″, the primary also having two much fainter components, one at a separation of 0.06″ and the other with an orbital period of 5.55 days.

Interesting variable stars in Scorpius include RR Scorpii, a Mira-type star (range 5.0–12.4, period about 281 days), and U Scorpii (range 8.7–19.3), a recurrent nova which is normally about eighteenth magnitude but flared up to ninth magnitude in 1863, 1906, 1936 and 1979. Other interesting objects include the naked-eye open clusters NGC 6231, which contains more than 100 stars (including many high-luminosity O- and B-type supergiants) of mostly tenth to thirteenth magnitude but with a dozen or so brighter than seventh magnitude, including ζ^1 Scorpii (magnitude 4.7), M7 (NGC 6475), which has more than 80 stars, mostly between seventh and tenth magnitude, and M6 (NGC 6405, the Butterfly Cluster), which also contains more than 80 stars, mostly between magnitudes 7 and 11. There are also two bright globular clusters: M4 (NGC 6121), which is sixth magnitude and located about 1.3° west of α Scorpii, and M80 (NGC 6093), which is seventh magnitude. Another interesting object is NGC 6302 (the Bug Nebula), a tenth-magnitude, elongated planetary nebula.

Also in Scorpius is Scorpius X-1, an x-ray binary and the brightest x-ray source in the sky.

See also: Antares, Scorpius X-1.

Scorpius X-1

The brightest cosmic x-ray source in the constellation of Scorpius and the first cosmic x-ray source to be discovered. Detected for the first time in 1962 by instrumentation carried to an altitude of 225 km by an Aerobee rocket, Scorpius X-1 is, apart from occasional transient sources, the brightest cosmic source of x-radiation in the sky.

It is a low-mass x-ray binary with an orbital period of 0.787 days and an x-ray luminosity of about 2×10^{37} watts (about 5000 times the optical luminosity of the Sun) that is located at a distance of about 2300 light-years. The binary is believed to consist of a low-mass star and a neutron star, the x-radiation being emitted from the surface of the neutron star and from its accretion disk.

Sculptor

(the Sculptor; abbrev. Scl, gen. Sculptoris; area 475 sq. deg.) A southern constellation which lies between Cetus and Phoenix, and culminates at midnight in late September. It was introduced as Apparatus Sculptoris (the Sculptor's Workshop) by the French astronomer Nicolas L de Lacaille (1713–62), who charted the southern sky in 1751–2.

An inconspicuous constellation, the brightest star in Sculptor is α Sculptoris, magnitude 4.3. Interesting stars in Sculptor include ε Sculptoris, a binary with pale yellow (F2) and yellow (G9) components, magnitudes 5.4 and 8.8, separation 4.9″, period about 1200 years, and R Sculptoris, a very red (C6) semiregular variable star (range 9.1–12.9, period about 370 days).

Other interesting objects include NGC 288, an eighth-magnitude globular cluster, the Sculptor Dwarf Galaxy (ESO 351-G30), a widely dispersed dwarf spheroidal galaxy in the Local Group, about 260 000 light-years distant, NGC 253 and NGC 55, eighth-magnitude edge-on spiral galaxies (both members of the Sculptor group, which is the nearest collection of galaxies to the Local Group, about 12 million light-years distant), and the Cartwheel Galaxy (ESO 350-G400), a fourteenth-magnitude ring galaxy with faint, radial 'spokes' bearing witness to a former collision.

The south galactic pole is located in Sculptor.

See also: Cartwheel Galaxy.

Scutum

(the Shield; abbrev. Sct, gen. Scuti; area 109 sq. deg.) A southern constellation which lies to the south-west of Aquila, and culminates at midnight in early July. It was introduced as Scutum Sobiescianum (Sobieski's Shield) by the astronomer Johannes Hevelius (1611–87) of Danzig (Gdansk) in 1684 in honor of Jan Sobieski III, king of Poland.

A small, inconspicuous constellation, the brightest star in Scutum is α Scuti, magnitude 3.9. There are no other stars brighter than magnitude 4.0. Interesting objects include the variable stars R Scuti (range 4.2–8.6, period about 147 days), an RV Tauri star, and δ Scuti (range 4.6–4.8, period 0.19 day), the prototype of a class of pulsating stars, and M11 (NGC 6705, the Wild Duck Cluster), a fan-shaped open cluster which contains more than 400 stars between eighth and fourteenth magnitude.

The Milky Way passes through Scutum and is particularly bright in the north-east of the constellation, where it is known as the Scutum Star Cloud.

sdO Stars

Subdwarfs of spectral type O (sdO stars) are hot evolved stars with a lower luminosity than main sequence O stars. The sdO stars cover a wide range in the HERTZSPRUNG–RUSSELL DIAGRAM (HRD, see figure 1). At lower luminosities and temperatures they form the extension of the subdwarfs of spectral type B (sdB), bounded by the extreme blue extension of the Horizontal Branch (EHB) and the helium main sequence (He-MS). At higher luminosities the sdOs are found up to the region of the central stars of planetary nebulae (CSPNe). Some of the most luminous sdOs are indeed associated with a planetary nebula.

The existence of the sdO stars is a challenge for stellar evolution theory since their location in the HRD is usually avoided by evolution tracks. Understanding the sdOs stars and inclusion of these stars in the overall picture of stellar evolution requires knowledge of their fundamental stellar parameters, i.e., the effective temperature, the surface gravity and the chemical composition, for a reasonably large sample of sdOs. This requires a search for these rare objects, the analysis of their spectra, and an interpretation of the results in the context of stellar evolution theory.

A further introduction to the evolution of low and intermediate mass stars can be found in the article HORIZONTAL-BRANCH STARS.

Many results for sdO stars are summarized in the proceedings from the Second and Third Conferences on Faint Blue Stars (FBS2, Philip *et al* 1987; FBS3, Philip *et al* 1997). A review on subdwarfs has been given by Heber (1992).

The search for sdO stars

Blue, i.e. hot, stars in the Galactic disk are mainly young main sequence O and B stars. In surveys at high Galactic latitudes, however, hot evolved stars dominate the stellar objects. A large number of surveys have been conducted, which are described in detail in the article BLUE STARS AT HIGH GALACTIC LATITUDES. A list of about 1000 sdO stars is provided by Kilkenny, Heber and Drilling (1987, FBS2). Recently, several sdO stars in globular clusters have been detected by the Ultraviolet Imaging Telescope. In the UV the majority of the cluster stars are invisible and only the UV bright stars like sdOs can be picked out easily.

Spectral analyses of sdO stars

In the last decade many of the sdO stars were analysed and high resolution optical and UV spectra allowed the determination of the chemical composition for selected sdOs. The major uncertainty originates from systematic differences between the results of different working groups, which are not resolved up to now. The latest results for nearly 50 sdO stars were presented by Lemke *et al* (1997, FBS3). They used non-LTE model atmospheres and a χ^2-fitting technique to determine effective temperatures, gravities and H/He abundances.

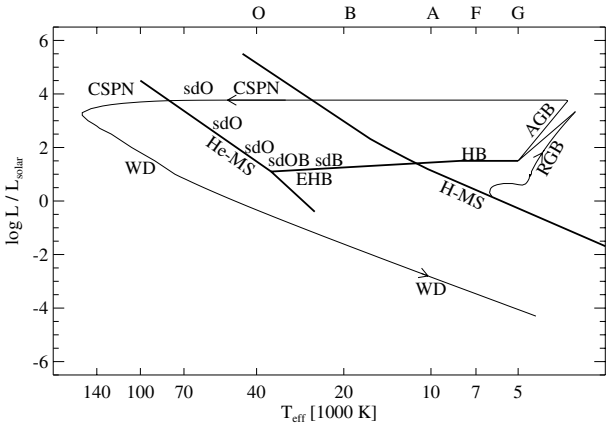

Figure 1. Schematic Hertzsprung–Russell diagram with an evolution track of a 1 $M_\odot$ star. H-MS, He-MS: hydrogen and helium main sequence; RGB, AGB: red and asymptotic giant branches; HB, EHB: horizontal and extreme horizontal branches; CSPN, WD, sdB, sdO: positions of central stars of planetary nebulae, white dwarfs, sdB and sdO stars, respectively.

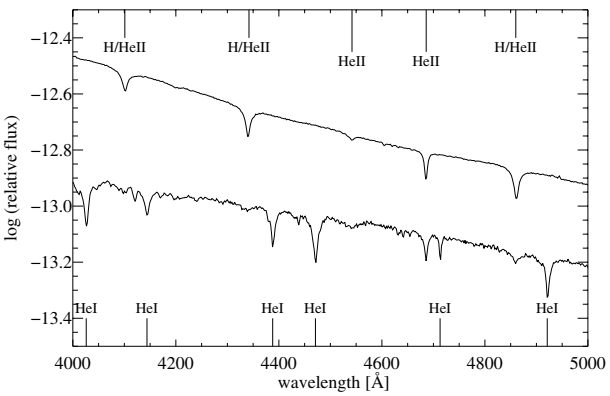

Figure 2. Sample spectra of a hot (80 000 K) sdO with normal H/He composition (top) and a cooler (40 000 K) helium-rich sdO (bottom).

Effective temperatures of sdO stars range from 40 000 K up to 100 000 K, the surface gravities range from $\log g = 4.5$ up to $\log g = 6.5$. The He/H ratio varies from about the solar value up to extreme helium-rich compositions with no hydrogen detectable. Besides these sdO stars there is also a group of helium-poor subdwarfs, mainly below 40 000 K and surface gravities around $\log g = 6$. In the literature these objects are also termed sdOB stars, emphasizing the close evolutionary connection with the sdBs.

Spectral characteristics

The spectral characteristics (see figure 2) of sdO stars in the optical spectrum are the presence of the 4686 Å line of singly ionized helium and the broad and shallow line profiles of the hydrogen Balmer series, which are superposed by the lines from the Pickering series of singly

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

ionized helium. The cooler members of the sdO group also display several spectral lines from neutral helium. At a spectral resolution of about 3 Å only a few lines from carbon or nitrogen can be detected in some sdO stars.

Model atmospheres for sdO stars
The progress of spectral analyses of sdO stars is very closely connected to the progress of modeling the atmospheres of hot stars. STELLAR ATMOSPHERES of solar type stars can in general be described with the assumption of local thermodynamic equilibrium (LTE) for the calculation of the population of all the atomic energy levels. In hotter stars this population is no longer determined by the local electron temperature but strongly influenced by the radiation field, which is non-local in those regions of the stars where the emergent spectrum is formed. Early analyses using LTE model atmospheres were therefore hampered by a poor reproduction of the observed spectra. The upcoming non-LTE stellar atmosphere models at the beginning of the seventies allowed for the first time a realistic modeling, however, taking into account only a basic model atom for hydrogen and helium. Greenstein and Sargent (1974) used these non-LTE models to determine effective temperatures and surface gravities for a large fraction of the sdOs known at that time. The abundances of heavier elements like carbon, nitrogen and oxygen could be determined only in calculations, where the structure of the atmosphere was kept fixed and the population of the element was iterated. This procedure cannot take into account the influence of the heavier elements on the structure of the model atmosphere. With the launch of the IUE satellite in 1978, access to the UV part of the spectra of sdOs became available and it soon became obvious that these stars exhibit an enormous number of metal lines in the UV. It was therefore clear that these numerous lines must significantly influence the atmospheric structure by blocking the transport of radiation, which can now be taken into account in state-of-the-art non-LTE model atmospheres (e.g. Haas *et al* 1996, Lanz *et al* 1997).

Chemical composition
Constraints for the evolution scenarios might be obtained from metal abundances. Several results are summarized by Dreizler (1993) and Bauer and Husfeld (1995). The latest analysis using HST spectra is presented by Lanz *et al* (1997). The metal abundances also show a large scatter. In general, the helium-rich sdO stars are also enriched in some metals, especially in carbon and nitrogen. This clearly indicates that the surface contains material burned in the CNO cycle as well as the products of the helium burning.

Elements like iron or nickel can be used as indicators for the metallicity since these elements are not produced in low mass stars. However, the Fe/Ni ratio can show deviations from the solar value, which very likely hints at diffusion processes, caused by gravitational settling and radiative levitation. In that case, the element composition would not allow conclusions on the evolutionary status since the abundance pattern can be completely altered by diffusion.

Mass loss
While main sequence O stars are known to exhibit a stellar wind, the atmospheres of most sdO stars can be regarded as hydrostatic. However, signatures of a stellar wind can be detected in the most luminous sdOs through P-Cygni profiles of UV resonance lines or through emission lines in the optical region. But even in these stars all other lines originate from the quasi-static layers of the atmosphere.

Evolutionary status

Even though sdO stars are predominantly found at high Galactic latitudes, investigation of the kinematics of these stars reveals an affiliation with the old disk population. Only a very small minority of the sdOs belongs to the POPULATION II, either through membership of a globular cluster or through a high radial velocity. No reliable scale height nor space density has been determined yet. In addition to spectroscopically determined parameters this would require knowledge of the masses to derive distances and the lifetime of the sdO stage. However, the evolutionary status must be identified beforehand.

Several evolutionary scenarios for single and binary stars exist to explain the sdO stars, which will be discussed in the following. The situation is complicated by the fact that the sdO stars cover a wide range in the HRD and comprise very different chemical compositions. In this context one question requires special attention: How did some sdOs become helium-rich?

Post-AGB scenario
The hottest and most luminous sdOs are found in the region of CSPNe. Therefore, those few sdOs with an associated planetary nebula can be identified as post-AGB stars evolving from the asymptotic giant branch (AGB) towards the white dwarfs. Heber and Hunger (1987, FBS2) suggested that the helium-rich sdOs in the region of the CSPNe may be linked to extreme helium and R CrB stars and could be products of a late helium shell flash scenario in which a star leaves the AGB, becomes a white dwarf and suffers a late helium shell flash. This takes the star back to the AGB and the post-AGB evolution repeats. The time span until the star is in the CSPNe range for the second time is sufficiently long to let the planetary nebula, ejected on first leaving the AGB, disappear.

Post-EHB scenario
The majority of the sdOs are found at the extreme end of the HB along the He-MS. The close proximity in the HRD to the sdB stars suggests an evolutionary connection between these two groups. Indeed, evolutionary tracks leaving the extreme end of the HB, the EHB (the position of the sdB stars) pass through the region in the HRD where sdOs are found. This scenario therefore is a plausible explanation, at least for many of the helium-normal sdOs. The post-EHB sdOs would have a very narrow mass range around $0.5\,M_{\odot}$.

It was long discussed how helium-rich sdO could be explained in this scenario, since a transition of a helium-poor sdB into a helium-rich sdO must have occurred then. Convective mixing caused by the helium ionization does not start off as long as the helium abundance is as low as in the sdB stars. A possible solution might be that the hydrogen-rich envelope, which was inert on the EHB, re-ignites during the post-EHB phase followed by excursions towards the AGB. The luminosity is not sufficient to let the star ascend the AGB and it therefore returns back to the sdO region. This excursion might cause deep mixing processes, which would help to explain the transition from hydrogen-rich sdBs to helium-rich sdOs.

UV bright stars in globular clusters have been analysed recently by Moehler *et al* (1998) and were identified as post-EHB or post-early AGB stars, the hotter ones being sdOs with a normal H/He ratio. The detection of sdOs in globular clusters is especially interesting in connection with the lower-than-expected detection rate of CSPNe in globular clusters. This matches the significantly higher population of the EHB where the stars evolve into post-EHB or post-early AGB stars, but cannot evolve to the top of the AGB and become CSPNe.

Delayed helium core flash scenario

The post-EHB scenario requires an exact tuning of the mass loss on the red giant branch (RGB) if the sdB stars, and therefore in the above picture also the sdOs, are explained by single star evolution. Mass loss on the RGB must be sufficiently high to remove most of the hydrogen-rich layer around the helium core at the moment the helium core ignites. Hydrogen layer masses below about $0.02\,M_{\odot}$ are required to have a sufficiently hot star on the HB. If, however, the mass loss on the RGB is too high then the helium core never reaches its ignition mass and the star ends as helium white dwarf without a HB phase. The scenario of the delayed helium flash as presented by Sweigart (1997, FBS3) opens the possibility to explain the cooler and most compact sdOs, especially the cluster of helium-rich sdOs around $T_{\rm eff} \approx 45\,000\,{\rm K}$ and $\log g \approx 5.8$, not covered by post-EHB tracks. If high mass loss terminated the RGB evolution before the helium core ignites, this ignition can still happen when the star is already on the white dwarf cooling sequence. The flash takes the star into the region of the sdOs also covering those compact sdOs which cannot be explained in the post-EHB scenario. Helium enrichment would be the consequence of mixing and burning of the remaining hydrogen-rich layer during the flash.

Subdwarfs and binary star evolution

Besides the evolution of single stars, binary evolution could also produce sdO stars. If two helium white dwarfs in a close binary system merge due to angular momentum loss through gravitational waves, the result could be an sdO star. The problem for this scenario is the observational lack of possible progenitor systems. The long time scale of this evolution would also imply membership of an old population. This scenario might therefore account for individual sdOs but not for the group in total.

Subdwarf O stars in binary systems are a valuable tool to check the evolutionary status since the stellar masses can be determined independently. However, mass transfer before the pre-subdwarf stage has to be excluded in order to test single-star scenarios. As discussed by Heber (1992), this seems not to be the case even in the widest system. On the other hand, the mass transfer is a plausible explanation for the helium enrichment through removal of the progenitor's envelope.

Seares, Frederick Hanley (1873–1964)

Born in Michigan, joined the original staff of the Mount Wilson Observatory. He used astrophotography of JACOBUS KAPTEYN's selected areas as part of the worldwide effort to determine the structure of the Galaxy, standardizing the stellar magnitude system. He extended it beyond the eighteenth magnitude by photographing stars of different brightnesses through wire screens and comparing the diffracted images of bright stars with the zeroth-order images of the faint ones. He used the body of data that this work produced to investigate the brightness of the Milky Way and the distribution and properties of its interstellar dust.

Season

Natural environmental and climatic changes occurring as a planet completes one orbit of the Sun. Any planet experiences seasons as long as its rotation axis is not at 90° to the plane of its orbit (the plane of the ecliptic, in the case of the Earth). Seasonal effects are very marked on Earth and Mars, especially at the poles. On Earth the four seasons—winter, spring, summer and autumn—begin in the Northern hemisphere on the winter solstice (December 22 or 23), the vernal equinox (March 20 or 21), the summer solstice, (June 21 or 22), and the autumnal equinox (September 22 or 23). In the Southern hemisphere, summer and winter are reversed, as are spring and autumn.

At the poles, the seasons consist of a short summer and a long winter when there is continuous darkness all winter and continuous daylight or twilight all summer. In low latitudes, where the range of the annual solar radiation and temperature cycle is very small, seasonal changes are based largely on rainy and dry periods.

Outside the tropics and the polar regions, seasons are distinguished by the temperature oscillating between a single maximum and a single minimum. This oscillation results from the annual variation in the angle at which the Sun's rays reach the Earth's surface and the duration of sunlight on the Earth's surface each day. Inclined about 66° 33′ to the orbital plane, the Earth's axis maintains a nearly constant orientation in space as it orbits the Sun. During the six-month half of each orbit when the North Pole is inclined toward the Sun, a point in the Northern hemisphere receives the Sun's rays at an angle closer to 90° than does a point in the Southern hemisphere. The result is greater heating and more hours of daylight in the Northern hemisphere than in the Southern hemisphere. During the following six months the conditions are reversed.

The amount of solar radiation arriving at the surface of a planet is also affected by the eccentricity of its orbit. Because the Earth currently reaches perihelion (closest approach to the Sun) in early January, the input of solar radiation to the Northern hemisphere during Northern hemisphere winter is slightly greater than the input to the Southern hemisphere during that hemisphere's winter. Conversely, the input of solar radiation to the Northern hemisphere in summer is less than to the Southern hemisphere in summer. Furthermore, because the Earth travels slightly faster along its orbit at perihelion than at aphelion, the Southern hemisphere summer is of marginally shorter duration than the Northern hemisphere summer. Because of its greater orbital eccentricity (0.0934, compared to 0.0167 for the Earth), these effects are more marked in the case of Mars.

Because the rotational axes of planets precess (undergo slow periodic changes in their orientation), the times at which planets reach perihelion or aphelion migrate slowly through the seasons; for example, in about 13 000 years' time, the Earth will reach perihelion during the Northern hemisphere summer. Furthermore, because of the gravitational influence of other solar system bodies, the axial inclinations and orbital eccentricities of the planets undergo slow, quasi-periodic changes that alter the input of solar energy at different latitudes during the different seasons and cause climatic changes. According to M Milankovich, the combination of these three cycles leads, from time to time, to a drop in the Earth's temperature that triggers the onset of ice ages. Mars experiences greater changes in axial inclination and orbital eccentricity than does the Earth.

Secchi, Angelo (1818–78)

Born in Reggio Emilia, became a Jesuit and was exiled with the rest of the order by Mazzini's Roman Republic. After a period at Georgetown Observatory, he returned to Italy in 1849 as director of the Roman College Observatory, constructing a new observatory dome on top of the main pillars of the incomplete church of Saint Ignazio. Secchi used its telescopes for solar and stellar research, one of the first astronomers to concentrate on physical properties rather than positions. He classified the spectra of over 4000 stars into five classes based on the appearance of the spectra (this work developed and superseded by the more detailed Harvard system of EDWARD PICKERING), and studied the planets. He discovered that Jupiter was gaseous. He drew the dark lines that join areas of Mars, and used the word canali, a direction taken up by SCHIAPARELLI.

Second of Arc

One second of angular measurement. Also known as 'arc second' (abbreviation 'arcsec') and denoted by the symbol $''$, a second of arc is one-sixtieth of a minute of arc (arcmin) which, in turn, is one-sixtieth of a degree. There are 3600 (60×60) seconds of arc in 1 degree and 206 265 seconds of arc in one radian.

Secondary Crater

A small crater formed on a planetary body by a block of ejecta thrown out during the excavation of a larger impact crater, the *primary crater*. Secondary craters from recent impact events, such as those associated with the lunar crater Tycho, tend to be more easily identifiable as secondary features. Some are clustered around the primary crater, and tend to be irregular, having been formed by low-angle, low-velocity impacts. Others, produced by ejecta on higher trajectories travelling faster, are found quite far away and tend to be more circular. They can occur as crater chains, as on the Moon for example (though some crater chains are volcanic in origin) and in the so-called intercrater plains of Mercury. Other bodies on which secondary craters have been identified include Ganymede, associated with the large multiringed impact feature Gilgamesh, and Europa, where they are presumed to have been formed by the impacts that produced large craters such as Pwyll.

Seeing

The sharpness of a telescope image determined by the degree of turbulence in the Earth's atmosphere.

Temperature alters the refractive index of air, so bubbles of air at different temperatures, blown by the wind across the aperture of a telescope, cause a distortion of its image of a star, much like the effect of wrinkled bathroom window glass. Physically the effect of inhomogeneous refractive index corrugates the incoming planar wave front from the star, and its image does not focus to a point (or to a near-point-like diffraction disk). A crucial quality is the size of the bubbles of inhomogeneous air relative to the aperture of the telescope. Small aperture telescopes view the star through not many bubbles and the effect of a single bubble is to tilt the incoming light beam. As the wind blows the bubbles across the telescope, the star image dances in the focal plane. As viewed in a very small telescope such as the eye, the star may twinkle a lot. By contrast, a large telescope views a star image through many bubbles and the image is stationary but diffuse. In the intermediate case, the image shows condensations or 'speckles'—the technique of speckle interferometry constitutes a way to sharpen the image.

Seeing is quoted in arc seconds across a star image. There is no clear convention whether the number quoted is the Full Width at Half Maximum, of the light distribution in the image, or the diameter of the circle enclosing 90% (or 95%, or 99%) of the radiant flux. Eye-estimates of seeing are not very reliable because the eye is a quick-response detector and picks out the brighter core of the image, minimizing the apparent size of the seeing disk.

Seeing is crucial to the performance of a telescope. For this reason, amateurs avoid placing telescopes near sources of heat (such as chimneys and houses) and seek country locations for their observations, and professionals place their telescopes on high mountains in undisturbed air, designing the observatory buildings and telescopes to minimize seeing induced by the equipment ('dome seeing').

Selene (Selenological and Engineering Explorer)

Japanese lunar exploration project conducted jointly by NASDA and the Institute of Space and Astronautical Science (ISAS). Launch is planned for 2003. Consists of a lunar polar orbiting satellite and a relay satellite. After one year, the polar orbiter's propulsion module will soft-land on the Moon. The major objectives are to obtain data necessary for clarifying the origin and evolution of the Moon, and to develop technologies vital for lunar exploration, such as soft landing technology.

Self-Organized Criticality and Turbulence in the Solar System and Beyond

Complexity, an ubiquitous phenomenon?

Forest fires, earthquakes, avalanches, solar flares and stellar flares caused by the collapse of ACCRETION DISKS all share common observable features. These systems do not appear to be in a single equilibrium. Rather, they migrate between many metastable states, releasing energy in an irregular, bursty manner. These energy release events, or avalanches, do not have the characteristic mean size, or timescale, that those seen in an equilibrium system would have. Instead their probability density functions are inverse power laws, $P(x) \sim x^{-s}$ where s is the exponent. In consequence, 'extreme' events (with large x) are thus much more probable than they would be in systems in equilibrium which exhibit Gaussian statistics ($P(x) \sim \exp(-x^2/\sigma^2)$).

A recent paradigm is that these non-equilibrium systems are highly correlated. In such complex systems the physics occurring on different scales is strongly coupled. As a consequence we say that the observed behavior is scaling, that is to say it is statistically self-similar, and on the average looks the same on any scale. The corollary of this is inverse power law statistics, and the presence of self-similarity (and possibly fractality, i.e. a non-integer dimension) in the spatiotemporal structure of the events themselves. This key aspect of the phenomenology arises from the nature of the coupling between processes on many scales, rather than from individual processes when understood in isolation. Thus, although these individual processes (say plasma instabilities or the point of ignition in forest fires) may be very different, the way in which processes on different scales couple may share the same mathematical description.

A topical, and in principle generic, paradigm that provides elements of a spatiotemporal description for such complex, highly correlated systems is that of self-organized criticality (SOC), introduced by Bak *et al* (1987). Essentially, such a system is high dimensional, with non-linear coupling between the many nodes of the system. Characteristically this coupling takes the form of a hysteresis. A local variable characterizing, say, stress in an earthquake model, or free energy in a plasma, is driven to increase, but the system does not relax until an (arbitrary) critical threshold, that is a threshold for instability, is exceeded. Once this threshold is exceeded, the system relaxes locally on a fast timescale to a value well below critical. This fast local reconfiguration may trigger instability in its vicinity, thus initiating an avalanche of energy release. The driven system then releases energy in bursts and crucially it does not relax back to an equilibrium ground state but, rather, returns after each avalanche to one of many metastable states. The avalanches then can occur on all sizes supported by the system and have no characteristic scale, instead exhibiting inverse power law statistics.

A related class of systems is that of turbulent fluids. Again, one in principle has a system of equations that specify the dynamics, the Navier–Stokes equation in the case of FLUID DYNAMICS or (in the case of a plasma on sufficiently large spatiotemporal scales) MAGNETOHYDRODYNAMICS (MHD). In practice, once a parameter characterizing the flow is increased beyond a certain threshold, the dynamics becomes highly irregular. In the 1940s Kolmogorov showed from energy and dimensionality considerations that turbulence should have a self-similar energy cascade. The resulting power laws in, for example, the wavenumber spectrum (k spectrum) have exponents which can be obtained from Kolmogorov's theory. A different approach in which there has also been considerable progress is to model the cascade in energy using dynamical systems techniques (see for example Bohr *et al* (1998) and references therein). These seek to describe the turbulent cascade in terms of the non-linear coupling of the different k shells. The relevance of SOC to these approaches is that it may provide insights that will lead to a spatiotemporal theory of turbulence that predicts not only the formation and evolution of spatial structure but also the scaling laws and the observed correlation in both space and time.

Self-organized criticality, the renormalization group approach

An elegant analytical framework for SOC is provided by the renormalization group (RG) procedure (for an introduction see Wilson (1979) and Sethna *et al* (2001); a detailed discussion of the method is given by Cardy (1996)). The key idea here is to consider the effect of coarse graining a physical system. This may be pictured either as examining the system averaged over a progressively longer and longer spatial scale or as stepping backwards from a given system so that the available resolution is progressively reduced. The mathematics of the renormalization procedure ('group' is in some ways a misnomer as the transformation does not have an inverse) essentially embodies a recurrence relation that describes any single step in the above coarse graining of a system. Importantly, the coarse graining may be applied in an abstract system space, where the coordinates are the various values of parameters in a given theoretical model or different models, or in real (configuration) space (see figures 4–6 of Sethna *et al* (2001)). We can specify a path (the renormalization flow) of the system in the corresponding RG space which has coordinates that essentially specify the number of times that the coarse graining operation has been applied. The system may be found to possess a fixed point in this RG space;

Copyright © Nature Publishing Group 2002

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

that is, the dynamics appears to be unchanged as we repeatedly coarse grain. If the renormalization is in real space, the implication of such a fixed point is that the dynamics must then be the same on all spatial scales under suitable rescaling; hence the dynamics is self-similar. In this case the RG will predict the exponent of the inverse power law statistics of event size and so forth (for an example applicable to THE MAGNETOSPHERE OF THE EARTH, see Tam *et al* (2000)). If the renormalization is in system space, the fixed point provides a fundamental prediction of the universality of the system; the different values of the many available parameters produce the same dynamics in the repeatedly coarse grained system and thus, although the microphysical processes may be very different, the macroscopic physics will be the same. An example here is the identical exponents describing the self-similar fluctuations in a liquid–gas critical point and a ferromagnetic critical point (Goldenfeld 1992). The RG thus provides the theoretical basis for understanding why universality, and self-similarity, can occur. Although it may appear that the microphysics has been 'lost' in this analysis this is not the case; instead, the physics on all scales is embodied in the recurrence relation that relates the physics on one scale to that of the next, more coarse-grained scale.

Renormalization (successive coarse graining) in configuration space of SOC models and some natural systems has revealed that the dynamics is governed by a fixed point and in this sense such systems are indeed critical. As a consequence, in the vicinity of the fixed point the avalanches have no characteristic scale, exhibiting inverse power law statistics with characteristic exponents. If the renormalization flow in system space is always towards the fixed point the system self-organizes towards criticality with weak dependence on tuning parameters (see also Jensen 1998) and independently of its starting point in the system space. In such a system, details of the microphysics, such as thresholds for local instability, would not strongly affect the macroscopic physics. Thus if a given system is tractable to RG approaches it is possible to analytically establish whether the system is in SOC and to predict the characteristic exponents of event statistics.

Unfortunately, many physical systems, and in particular the hierarchy of plasma equations, are so far intractable to the RG. An approach is then to construct a simple analytical model for the system (a sandpile or 'avalanche' model, say) that preserves the conservation properties and symmetries of the physical system of interest but which is also tractable to the RG.

Numerical approaches

The intermediate step is to construct simple numerical models which mimic the physical system and which are computationally tractable, that is they can be run on a sufficiently large spatial grid, and for a sufficient time, to test for self-similarity, i.e. to establish power law statistics in events. For a discussion of numerical, as well as analytical, approaches to SOC see Jensen (1998) and for a review relevant to magnetospheric physics see Chapman and Watkins (2001). Once the dynamics of these simple systems has been understood, one can then in principle use RG to establish whether the simple model is in the same universality class as the physical system of interest. In practice a more readily achievable goal is to use real space RG to obtain the scaling predicted by the model. This can then be directly compared with observations of the physical system. Simple numerical models also allow the effect of finite-sized systems on the dynamics to be explored; the real space RG naturally only treats systems where length scales can be taken arbitrarily large (see, for example, Tam *et al* (2000)).

The numerical sandpile approach parallels that of shell models for turbulence, where numerical models (difference equations) in k space describe an energy cascade from one k mode to the next; these are constructed to preserve the symmetries and conservation properties of the Navier–Stokes equations (see Bohr *et al* (1998) for a discussion). SOC models may also be contrasted with other numerical schemes where difference equations locally couple the nodes (typically spatial coordinates at which fields are defined) on the grid. Coupled map lattices use chaotic maps to specify the local spatiotemporal evolution of the system; these systems can exhibit self-similarity but require fine tuning of the parameter of the map (for a review see Kaneko (1993)). The perhaps more familiar example is where the local difference equations are obtained directly from the governing equations of the system (say the MHD equations) essentially by Taylor expansion. Provided that the difference scheme captures the essential physics of MHD, and a sufficiently large computational grid is used, these can generate self-similar dynamics in the form of turbulent cascades (for a recent example see Müller and Biskamp (2000)). Directly physically motivated simulations of this type can provide insight into the spatiotemporal structure and in particular the role of topology in an evolving turbulent system. Unless tractable to the RG, they cannot establish whether the self-similarity found in the simulation is a universal property of turbulence or is unique to the particular conditions and geometry of the simulation.

Solar system plasmas: complicated or complex?

Observational motivation for SOC in the solar system and beyond currently centers around evidence of self-similarity and also evidence of intermittent, bursty anomalous transport (seen also in artificial plasma confinement systems such as Tokamaks, see Chapman *et al*

Copyright © Nature Publishing Group 2002

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

(2001)). A significant difficulty is that establishing a power law in the statistics of events requires large datasets with a dynamic range spanning several orders of magnitude. Nevertheless, self-similar statistics of bursty energy release have been found in x-ray flux from solar flares over several orders of magnitude (see, for example, Crosby *et al* (1993) and references therein); this prompts comparisons with simple avalanche models (see, for example, Lu and Hamilton (1991)). Self-similarity, and, by implication, SOC, has also been inferred from the power spectra of stellar accretion disks (e.g. Mineshige *et al* 1994). In the case of the Earth's magnetosphere, the challenge is to find an observable that unambiguously contains information on all the avalanches hypothesized to be occurring in the system and an attempt has been made with images of patches of activity in the AURORA (Lui *et al* 2000)). This followed the observation of power law power spectra of indices (AE – auroral electrojet) which characterize magnetic perturbation underneath the auroral oval. However, power laws are not a unique property of SOC (for a review of other processes see Sornette (2000)). In particular, power law power spectra are consistent with a colored noise process (for a magnetospheric example in the context of chaos see Shan *et al* (1991)).

Progress is thus needed on two fronts. First, a combination of numerical experiments and RG analysis is needed to make predictions of quantitative observables such as the exponents of inverse power law statistics of events. The theory needs to establish that non-trivial self-similarity arises from criticality as a natural emergent property of the multiscale plasma process at hand. Second, unambiguous observables with sufficient dynamic range are needed to test the prediction of scaling behavior. The promise of SOC is that it may provide a unifying theory of anomalous plasma transport in natural astrophysical plasma confinement systems.

Separation

The angular distance between two objects, measured in arc units on the celestial sphere. This is most commonly used in measurements of double and multiple stars, and together with the position angle defines the observed form of the system. It is also used to determine the observed distance of a satellite from its primary planet.

Serpens

(the Serpent; abbrev. Ser, gen. Serpentis; total area 637 sq. deg.) A constellation that is unique in that it is divided into two: Serpens Caput (the Serpent's Head; area 429 sq. deg.), which lies mostly in the northern sky between Böotes and Hercules, and culminates at midnight in mid-May, and Serpens Cauda (the Serpent's tail; area 208 sq. deg.), which lies mostly in the southern sky between Ophiuchus and Scutum, and culminates at midnight in late June. It represents the huge snake held by Ophiuchus, the Serpent-bearer, around whose body it is coiled. The brightest stars of Serpens were cataloged by Ptolemy (*c.* AD 100–175) in the *Almagest*.

A rather inconspicuous constellation, the brightest stars in Serpens are α Serpentis (Unukalhai), magnitude 2.6, η Serpentis, magnitude 3.2, μ Serpentis, magnitude 3.5, and ξ Serpentis, also magnitude 3.5. There are four other stars brighter than magnitude 4.0. Interesting stars in Serpens include θ Serpentis (Alya), a wide double with white (A5) components, magnitudes 4.6 and 5.0, separation 22″, that have the same proper motion, δ Serpentis, a close binary with white (A9 and A7) components, magnitudes 4.2 and 5.3, separation 4.0″, R Serpentis, a Mira-type variable (range 5.2–14.4, period about 356 days), and W Serpentis, an Algol-type eclipsing binary (range 8.4–10.2, period 14.15 days).

Other interesting objects in Serpens include M5 (NGC 5904), a sixth-magnitude globular cluster, and IC 4703 (the Eagle Nebula), an emission nebula which contains the open cluster M16 (NGC 6611) of more than 60 stars fainter than eighth magnitude.

SETI Institute

The SETI Institute, founded in 1984, is a private non-profit center for research and education related to the scientific search for extraterrestrial life.

The SETI Institute currently encompasses more than 30 research projects. The most visible of these is Project Phoenix, the world's most sensitive search for extraterrestrial intelligence ('SETI'). Begun in 1995 at the Parkes 210 ft radiotelescope in Australia, Phoenix moved to the 140 ft telescope at the National Radio Astronomy Observatory in Green Bank, West Virginia in 1996. From fall of 1998 through the summer of 2003, observations will take place at the 1000 ft Arecibo radiotelescope in Puerto Rico. Project Phoenix is a targeted search which scans billions of frequency channels for narrow-band continuous wave and pulsed signals from nearby Sun-like stars. It commands slightly more than half of the Institute's total operation, and is privately funded. The Institute is now developing and prototyping new system designs for next-generation SETI.

The balance of research projects at the SETI Institute fall within the Institute's Center for the Study of Life in the Universe. These projects investigate the origin and evolution of life on Earth and possibilities for life elsewhere. Most of this work is currently funded through competitively won peer-reviewed government research grants.

Severin [Soerensen, Longomontanus], Christian (1562–1647)

Danish astronomer, born in Longberg (from which his Latin name), Jutland, studied astronomy under TYCHO BRAHE, became professor of mathematics and astronomy at Copenhagen. His work, *Astronomia Danica*, was effectively Tycho Brahe's legacy, and resolutely maintained the geocentric theory of the planets in the Tychonic version (the Moon and Sun revolving round the stationary Earth and the remaining planets revolving around the Sun). His only concession to COPERNICUS was to introduce the concept of the rotation of the Earth on its axis.

Sextans

(the Sextant; abbrev. Sex, gen. Sextantis; area 314 sq. deg.) An equatorial constellation which lies between Leo and Hydra, and culminates at midnight in late February. It was introduced as Sextans Uraniae (Urania's Sextant) to commemorate the astronomical sextant (which is larger than the later marine sextant) by the astronomer Johannes Hevelius (1611–87) of Danzig (Gdansk), who included it in his atlas *Firmamentum Sobiescianum sive Uranographia* of 1687.

A small, insignificant constellation, the brightest star in Sextans is of magnitude 4.5. Interesting objects include NGC 3115 (the Spindle Galaxy), a ninth-magnitude lenticular galaxy.

Seyfert Galaxies

In many respects Seyfert galaxies are similar to any other galaxy, except their nuclear regions show unusual properties: they can be much brighter and their spectra show strong emission lines of high excitation. Such nuclei are called 'active', and so Seyfert galaxies belong to the wider category of 'ACTIVE GALAXIES' or, more specifically, they have 'ACTIVE GALACTIC NUCLEI' (AGN). Seyferts were, in fact, the first type of active galaxy to be discovered.

In the zoo of AGNs the power of the nuclear activity spans a wide range. Within this zoo, Seyferts show intermediate levels of activity, being more powerful than LINER galaxies but less powerful than QUASARS. Seyferts also join the majority of active galaxies in being 'radio-quiet', with radio luminosities 10^3–10^4 times weaker than the 'radio loud' category, which includes RADIO GALAXIES and radio quasars.

Over the past 20 years much effort has gone into finding Seyfert galaxies amongst the more normal galaxy population. Efficient ways to detect Seyferts include looking specifically for galaxies with bright UV emission, bright x-ray emission, or unusual far-infrared colors, since these are common characteristics of Seyferts. The fraction of galaxies with active nuclei depends on the level of activity: moderate luminosity Seyferts make up $\sim$ 1–2% of nearby bright galaxies, lower luminosity Seyferts make up $\sim$ 10%, while LINERs make up $\sim$ 40%. Currently, about 800 Seyferts are known, though the number continues to rise.

From a wide range of studies, a picture has emerged of the structure of the central regions of Seyferts. Briefly, the gravitational field of a supermassive (10^6–10^9 $M_\odot$) black hole provides the ultimate energy source, as gas falls inwards via a luminous accretion disk (see SUPERMASSIVE BLACK HOLES IN AGN). A small region of fast moving clouds surrounds this central engine, spanning a few light days or weeks, while a larger region of slower moving clouds extends out a few hundred to a few thousand light years. In some cases, oppositely directed collimated jets of low density gas plow into the surrounding galaxy, accelerating the interstellar medium and creating jet-like or linear radio structures. In at least some Seyferts, dense gas and dust shroud the innermost regions, hiding them from our direct view, though the nuclear radiation escapes in other directions to light up gas and dust residing much further out in the galaxy.

The conditions that give rise to Seyfert activity are still under debate. While Seyferts are found in a wide range of galaxy types, they are more commonly found in reasonably luminous early-type spirals (e.g. types S0/a, Sa, Sb in the Hubble classification scheme). It seems, therefore, that prerequisites favoring Seyfert activity include a massive galaxy bulge and the presence of an interstellar medium. There is also evidence that Seyferts prefer galaxies with an asymmetric gravitational field arising from a bar or other distortion, possibly induced by a nearby companion galaxy. Such distortions are thought to be instrumental in funneling gas down to the nuclear regions where it can then fuel the central black hole.

Discovery, classification and detection

The early identification of nearby Seyfert galaxies rested on two observational properties—their unusual nuclear spectra and their unusual nuclear brightness. While studying galaxy spectra for his PhD work in 1908, Fath noted strong emission lines in the spectrum of the nucleus of NGC 1068. These observations were confirmed in 1917 by Slipher and by 1926 Hubble had added two more galaxies with similar spectra: NGC 4051 and NGC 4151. In 1932 Humason noted that NGC 1275 had a bright starlike center, but it wasn't until 1943 that CARL SEYFERT recognized a distinct class of galaxies with unusually bright and concentrated nuclei, and studied in detail six of the 12 then known cases (NGC 1068, 1275, 3516, 4051, 4151, 7469), leading to the group's name: Seyfert galaxies (see figure 1). Seyfert's spectra showed emission lines which were not only unusually strong, but also unusually wide. Interpreting the width of the spectral lines as Doppler shifts caused by motion of the ionized (line emitting) gas implied gas velocities in some objects of several thousand km s^{-1}, far higher than velocities found in normal galaxies. A further subtlety Seyfert noticed was that in some objects the hydrogen lines were broader than the other lines.

Little work was done until the 1960s, when it became clear that Seyfert galaxies shared a number of properties with the then recently discovered quasars. At this time, quasars posed a serious theoretical puzzle. While their high REDSHIFTS implied great distance and therefore high luminosity, their brightness had been found to vary from month to month, indicating that the region producing all this energy was only a few light months across—tiny compared to the rest of the galaxy. The puzzle of how so much energy could emerge from so small a volume was sufficiently acute that some astronomers even questioned whether the quasar redshifts were true indicators of distance, leading to the so-called 'redshift controversy'. Although this controversy has since been resolved in favor of large distances it might never have been as problematic if Seyfert galaxies had been better studied in the early 1960s, since they are clearly low redshift counterparts to the quasars. Not only are their spectra basically similar, but in 1968 NGC 4151 was found to vary in brightness, confirming a highly compact nuclear energy source. As more Seyferts and quasars were discovered, their separation in luminosity narrowed and finally even overlapped. Continuity had been established and, for most astronomers, the reality of the quasar distances and luminosities was no longer in doubt.

In 1974, Khachikian and Weedman identified two types of Seyfert galaxy on the basis of the widths of the nuclear emission lines. Figure 2 shows example spectra of each Seyfert type. While spectra of type 2 Seyferts have a single set of relatively narrow emission lines, in the spectra of type 1 Seyferts the hydrogen and helium

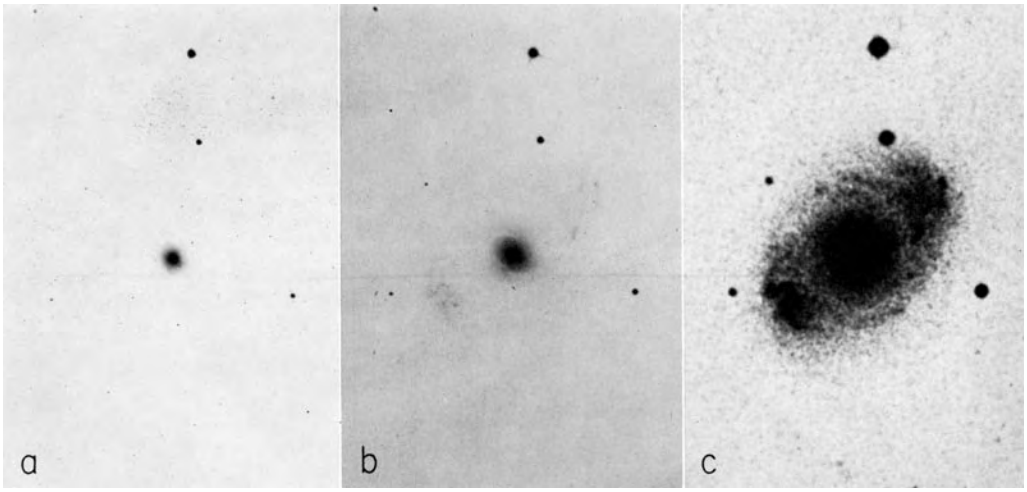

Figure 1. Three photographs of NGC 4151 taken with increasing exposures (a, b, c) showing its unusually bright nucleus—an important characteristic used in the early identification of Seyfert galaxies. (Taken from Morgan W W 1968 *Astrophys. J.* **153** 27)

lines have an additional much broader component. In the simplest cases, the broad component is either absent (Seyfert 2) or strong and dominant (Seyfert 1). With better data it became clear that there is a wide range in the relative strength of the broad and narrow emission lines, and this led Osterbrock in 1981 to refine the Seyfert classification by introducing intermediate types. A good place to establish the classification is with the hydrogen Hβ line at rest wavelength 4861 Å. As the broad component of Hβ becomes weaker relative to the narrow component, the Seyfert type changes from 1 to 1.2 to 1.5 to 1.8. For Seyfert 1.8 galaxies, weak broad wings are just visible at the base of Hβ while for Seyfert 1.9 galaxies they are only visible on the Hα emission line at 6563 Å. In practice, these Seyfert sub-types have not been formally defined but instead give an overall indication of the degree to which the broad component is present.

Although there are a number of Seyfert properties that depend on Seyfert type, perhaps the most noticeable is the 'white light' continuum coming from the nucleus. In normal galaxies the nuclear continuum is mostly starlight, but in active galaxies there can be additional emission, often blue in color and with few or no absorption features. This component is much stronger in Seyfert 1s, weaker in Seyfert 2s, and may even be undetectable in the lowest luminosity Seyfert 2s. Although we refer here to the optical continuum emission, this component extends into the UV and x-ray, and so emission in these spectral bands can also be quite different for Seyfert 1s and Seyfert 2s.

Bearing in mind the principal features which distinguish Seyfert spectra from normal galaxy spectra—strong broad emission lines and a blue continuum—we can now follow the history of how Seyferts have been identified over the past 40 years.

As outlined above, the first Seyferts were discovered essentially by accident when a galaxy spectrum was noted as being unusual. The first survey which identified many Seyferts was that of Markarian and collaborators at the Byurakan Observatory in Armenia, during the period 1962 to 1981. This survey used a technique known as Objective Prism Spectroscopy to find galaxies with unusually blue continuum emission. The telescope was a 1.3 meter Schmidt telescope with a thin prism bolted over the entrance aperture. This combination gives relatively wide field photographs in which each star and galaxy appears as a small spectrum. In this way, the spectra of many galaxies can be studied quickly, and those which appear unusual noted and listed. The survey covered $\sim$ 10 000 square degrees and yielded 1500 galaxies with blue continua, of which $\sim$ 10% were Seyferts (the remainder were mainly STARBURST GALAXIES, blue because of the presence of young massive O and B type stars). Because of the emphasis on blue continuum, the Markarian Seyferts contain a relatively high proportion of Seyfert 1s (about 50%) and rather luminous Seyfert 2s.

Since x-ray emission is common in active galaxies, x-ray surveys provide an effective means to find Seyferts. Starting in the late 1970s surveys have included those of the Ariel V, HEAO-1, Einstein and ROSAT satellites. Some of these were all-sky surveys, some included deeper pointed observations, some were sensitive to hard x-rays (2–10 keV) and others to soft x-rays ($\sim$ 0.2–4 keV). In general, x-ray surveys tend to find Seyfert 1s since their nuclear continuum emission is stronger than in Seyfert 2s.

In 1982, the IRAS satellite provided a huge list of galaxies which were relatively bright in the far infrared (25–100 μm). Although bright infrared flux by itself is no guarantee of Seyfert activity, the 'color' of the infrared emission can help distinguish between Seyfert and normal galaxies: normal galaxies have colder dust ($\sim$ 30 K) than Seyfert galaxies ($\sim$ 100–300 K) in which nuclear activity provides an additional heating source. Thus, IRAS-selected galaxies with 'warm spectra' have yielded many Seyferts.

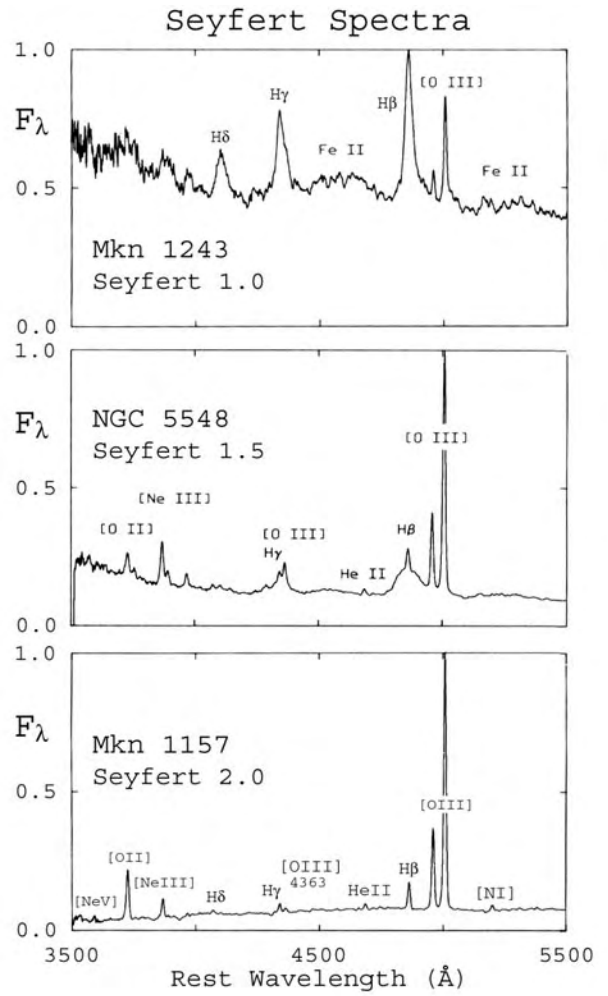

Figure 2. Spectra of three Seyfert galaxies illustrating the difference between Seyfert 1, 1.5 and 2 classes. Principal emission lines are labeled, with square brackets indicating forbidden lines. (Adapted from Osterbrock D E 1984 *Quart. J. R. Astron. Soc.* **25** 1.)

Since Seyferts belong to the radio-quiet group of active galaxies, radio surveys at high flux levels tend not to find Seyferts, but rather radio galaxies. Deeper radio surveys, however, do pick up more Seyferts but along with many star-forming galaxies. On further study, the presence of a compact core with flatter spectral index increases the chance that the galaxy is a Seyfert.

Perhaps the most reliable method of finding Seyferts, though also the least efficient, is optical spectroscopy of galactic nuclei. In the early 1990s the CfA redshift survey of about 2000 galaxies brighter than about magnitude 14–15 found about 2.5% to be Seyferts with an even mix of Seyfert 1s and 2s. Using smaller apertures and higher quality data, the deep Palomar survey of the nuclei of nearly 500 bright galaxies from the RSA catalogue yields about 10% Seyferts, including many of lower luminosity. In the near future, the SLOAN DIGITAL SKY SURVEY will surely find many more.

A catalog of all known Seyferts has been maintained by Veron-Cetty and Veron, and at its last edition (1998) about 790 Seyferts were listed with redshifts < 0.1 and brighter than 17^{m} in V.

Overall structure and geometry

In this section we give a brief outline, without justification, of the basic structures found in Seyfert galaxies; brief because similar material is given elsewhere in this encyclopedia and also because more detailed descriptions of some of the structures are given in subsequent sections.

Figure 3 gives a cartoon of the structures nested from innermost to outermost. The region sizes probably scale with luminosity, larger for quasars and smaller for low luminosity Seyferts and LINERs. The values given are rough guides for the case of moderate luminosity Seyferts.

The ultimate origin for the energy which drives nuclear activity is thought to lie in the gravitational field of a central supermassive black hole of mass $\sim 10^7$–$10^8\,M_\odot$. Gas falls into the black hole via an accretion disk, which radiates powerfully across much of the electromagnetic spectrum. The disk may span from a few Schwarzschild radii to a few thousand Schwarzschild radii, probably with x-ray emission coming from the inner parts, UV and optical from further out. It is this radiation which floods out into the galaxy and ionizes any surrounding gas, causing it to radiate emission lines. The innermost region of ionized gas resides a few light days from the center, and contains gas with density $\sim 10^9$–10^{12} atom cm^{-3} moving with speeds of a few thousand km s^{-1}. Doppler shifts therefore lead to broad emission lines—hence the name: Broad Line Region (BLR). Outside the BLR, on scales from one to a few pc lies thick dense gas, possibly in the form of a torus. This gas blocks radiation coming from the innermost regions, which can only escape out of the equatorial plane along the torus axis. This partially collimated radiation field emerges further into the galaxy to ionize gas residing in a region out to a few kpc. In this region, the gas has a lower density $\sim 10^2$–10^6 atom cm^{-3} and moves with speeds of a few hundred km s^{-1}, leading to narrower emission lines—hence the name: Narrow Line Region (NLR). Because of the partially collimated radiation field, the NLR often appears elongated or even biconical, with axis matching that of the central radiation field. When a radio source is present it is often elongated, aligned with the NLR axis, and has approximately the same size. The radio source emerges from the inner regions as a bipolar flow, accelerating and possibly shocking some of the gas in the NLR. The entire NLR and associated radio structure usually fill a region a few kpc across within the bulge of the host galaxy, but randomly aligned with respect to obvious galactic structures and orientation. If there is a more extended gaseous component, it can be illuminated by the central ionizing radiation field, leading to faint extended emission, sometimes showing conical or biconical form. This is the so-called Extended Narrow Line Region (ENLR).

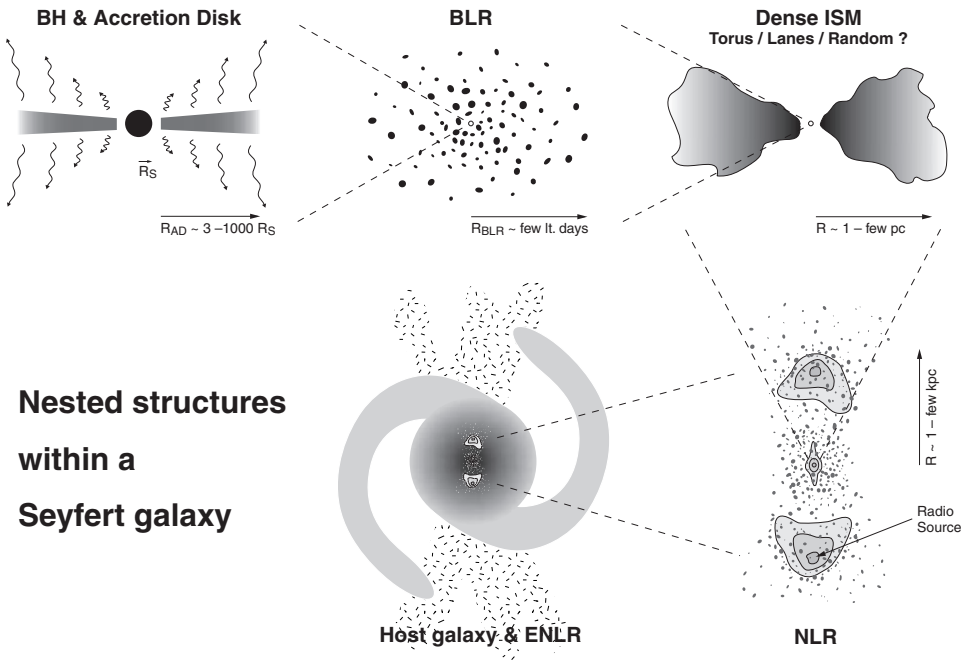

Figure 3. Cartoon illustrating the nested structures thought to be present within Seyfert galaxies.

Inherent in this picture is a lack of spherical symmetry, rooted in the anisotropic emergence of both radiation and radio emitting flows. The origin of the anisotropy might arise in either of two ways: (a) an intrinsic nuclear axis perhaps defined by the black hole spin and/or the accretion disk, and (b) partial obscuration by dense gas which blocks radiation in some directions but not in others. For Seyferts, partial obscuration is thought to be important. The simplest geometry envisioned is a thick disk or torus a few parsecs in size and aligned with the central engine axis. More recently, images from the Hubble Space Telescope (HST) have shown that dust lanes and filaments are common in the central few hundred parsecs, particularly in Seyfert 2s, raising the possibility that less coherent obscuration on these larger scales might also be important. Either way, the fact that the nuclear radiation can only emerge along particular lines of sight raises an interesting possibility which was first noted in 1978 by Osterbrock: namely, that Seyfert 2s might actually *be* Seyfert 1s but oriented in such a way that our view to the central region is blocked. Stated slightly differently, the same Seyfert galaxy might appear as a Seyfert 1 from some directions and a Seyfert 2 from others. This constitutes a 'Unification' scheme, since apparently different classes of objects are 'unified' into a single class. The important topic of unification arises in a number of contexts in the study of active galaxies and is discussed at length in ACTIVE GALAXIES: UNIFIED MODEL. Here we give a brief outline of the evidence supporting the particular case that many (though perhaps not all) Seyfert 2s are in fact hidden Seyfert 1s.

First, the emission line regions of Seyfert 2s, on both large scales (ENLR) and small scales (NLR), are often elongated, with a subset showing sharp edges and even conical or biconical form. These patterns are consistent with dense nuclear gas casting shadows in a strong central ionizing radiation field. When visible, the cone opening angles are $\sim 40°$–$80°$, suggesting $\sim 25\%$ of the surrounding sky sees the nuclear regions. Good examples of this are found in NCG 1068, NGC 5252, MKN 78, MKN 573.

Extending this topic further, one can use spectroscopy of the ionized gas to show that *it* sees a significantly brighter central radiation source than *we* see. There are two approaches. In the first, emission line strengths from extended gas are used to infer both the gas density and its degree of ionization. Knowing the distance between this gas and the central source then allows one to estimate the (ionizing) luminosity of the central source. This luminosity is often significantly greater than the luminosity we see directly, along our line of sight. The second approach uses the total Hβ luminosity coming from all regions to estimate the total ionizing luminosity of the central source. This luminosity is again often found to be significantly greater than the luminosity we infer from our own line of sight to the nucleus.

The third and perhaps most dramatic piece of evidence involves taking spectra of light that was initially moving out of the nucleus in one direction but then got reflected into our line of sight. This provides a sort of periscope, allowing one to look around a corner and into the nucleus from a different direction. The mirrors of the periscope are dust particles or electrons in the surrounding gas which scatter light in all directions, some

Dirac House, Temple Back, Bristol, BS1 6BE, UK

of which comes towards us. Since the scattered light is so faint compared to the normal light we need a way to isolate it. Fortunately, the scattering process also induces polarization, and so a spectrum of the polarized light shows just the scattered component. Remarkably, for many of the brighter Seyfert 2s these polarized light spectra show Seyfert 1 form: strong non-stellar continuum and broad hydrogen and helium lines. The classic discovery was for NGC 1068 by Antonucci and Miller in 1983, but since then many other examples have been found.

A fourth approach is to compare the nuclear x-ray emission of Seyfert 1s and 2s. Consistent with unification, soft x-ray spectra show significant absorption towards Seyfert 2s but little or none towards Seyfert 1s. Furthermore, at higher x-ray energies where absorption isn't important, the spectra of Seyfert 1s and 2s are often quite similar, with ratios of x-ray to optical flux much higher for the Seyfert 2s, as expected if the optical emission is blocked but the hard x-rays are not.

Finally, there is some evidence for the nuclear obscuring material itself. When water masers are detected, they tend to be in Seyfert 2s. These sources form in dense warm molecular gas with long paths in our line of sight, consistent with an edge-on disk geometry. Also, infrared spectra are often dominated by thermal emission from warm dust. Although some of this originates on NLR scales, some comes from much smaller scales. The fact that the total luminosity of many Seyferts, particularly Seyfert 2s, is dominated by the thermal infrared is consistent with the obscuration picture: much of the nuclear luminosity is absorbed by gas and dust whose principal mode of cooling is in the far infrared.

Assuming, for the moment, that all Seyfert 2s contain hidden Seyfert 1s, then we can ascertain the extent of the obscuration by comparing the relative number of Seyfert 2s (obscured) with Seyfert 1s (unobscured). In practice, it is important (and difficult) to select an unbiased sample of Seyferts using a property that is *not* thought to depend on orientation. Possibilities include radio flux, far-infrared flux, host galaxy magnitude, and narrow emission line flux, though none are ideal. With some uncertainty, the ratio of Seyfert 2s to Seyfert 1s found in such samples is roughly 2–5 to 1, suggesting $\sim$ 20–30% of the sky sees an unobscured view of the nucleus, consistent with other estimates based on the opening angle of emission line cones.

Whether *all* Seyfert 2s contain hidden Seyfert 1s is still an open question. Arguments against full unification of the two classes focus either on the absence of expected properties (for example, most Seyfert 2s have lower polarization than expected), or the fact that properties which should be the same in Seyfert 1s and 2s are not (for example, host galaxy morphology, and possibly radio luminosity).

Relation of Seyferts to other AGN

To the newcomer, it may seem that there are an annoyingly large number of names for different classes of active galaxy, of which 'Seyferts' are only one class. This situation has arisen for a couple of reasons: (a) nuclear activity seems to have some genuine range of character, and (b) historical development is never clean and different approaches have naturally focused on different manifestations of activity. In hindsight, it is now possible to group the various categories in a more or less natural way which depends on two or three fundamental aspects of the activity itself: total luminosity, radio luminosity and variability. While these aspects are discussed in ACTIVE GALAXIES: OVERVIEW and ACTIVE GALACTIC NUCLEI: VARIABILITY, here we give a brief overview of the different classes of AGN, intending to locate Seyferts in their proper place.

Consider first the enormous range in total luminosity of AGN: $\sim 10^{39}$ erg s^{-1} ($M_{\rm B} \sim -10$) at the lowest detectable end, up to $\sim 10^{47}$ erg s^{-1} ($M_{\rm B} \sim -30$) at the highest. Seyferts span the low to intermediate range, overlapping somewhat on the high end with quasars. Since it now seems that Seyferts and quasars form a continuous physical sequence, any attempt at a formal separation is somewhat arbitrary. Although a morphological criterion is usually adequate (quasars have point-like appearance) close scrutiny of low redshift quasars often reveals galactic 'fuzz' in ground-based images or clear host galaxies in HST images. For this reason, a luminosity criterion is sometimes chosen to delineate Seyferts and quasars. There is no consensus, but threshold values of $M_{\rm B} \sim -23$ or $L_{\rm B} \sim 10^{44}$ erg s^{-1} are typical. While Seyferts and quasars may be physically similar, differences do seem to occur with increasing luminosity, including longer variability timescales indicating larger emission regions, the apparent loss of the 'type 2' class, and some line strength changes including the relative weakening of both broad and especially narrow lines relative to the continuum.

Turning to lower luminosities, although one of the lowest luminosity AGNs is in fact a Seyfert (NGC 4395, $M_{\rm B\ nuc} \sim -10$) most of the low luminosity AGNs belong to the 'LINER' class. This group was originally identified by Heckman in 1980 from a spectroscopic survey of a large number of bright nearby galaxies. A high fraction were found to have weak emission with low overall degree of ionization, hence the name: Low Ionization Nuclear Emission Line Regions, or LINERs. The exact nature of LINERs is still unclear, with evidence for an active nucleus in at least $\sim$ 20%: a compact nuclear UV source seen in HST images; a compact though weak nuclear radio source; or weak broad line emission visible at the base of Hα. A major uncertainty is the ionization mechanism for the gas. Possibilities include shocks or photoionization by either a weak nuclear UV source, very hot young stars or very hot evolved stars.

Shortly after the identification of LINERs, a method for classifying emission line regions was introduced by Baldwin, Phillips and Terlevich and subsequently refined by Veilleux and Osterbrock. They used a number of diagrams which plotted the ratio of one pair of emission line fluxes against another pair. Figure 4 shows one of these diagrams and nicely illustrates how three major

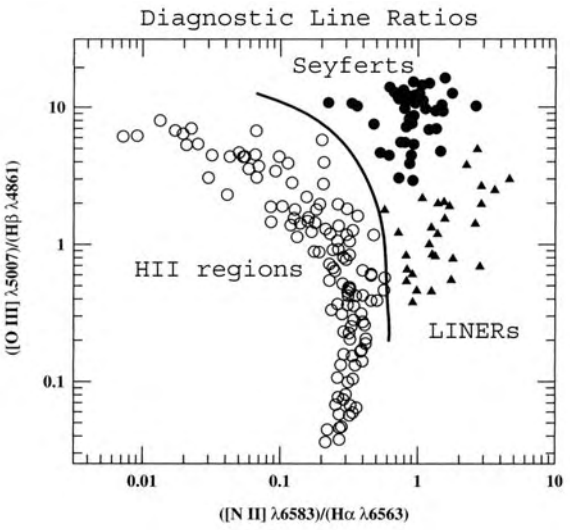

Figure 4. One of several useful diagnostic diagrams which help distinguish between different classes of emission line object. (Adapted from Peterson B M 1997 *An Introduction to Active Galactic Nuclei* (Cambridge University Press), figure 2.3, p 26).

emission region types occupy different places on the diagram; in this case Seyferts separate from LINERs around [OIII] $\lambda 5007/\mathrm{H}\beta \sim 3$ while Seyferts and LINERs separate from H II regions around [NII] $\lambda 6584/\mathrm{H}\alpha \sim 0.6$. These line ratio diagrams also provide a suitable place to compare observations with theoretical models. For example, the H II REGION sequence matches models of gas clouds with a range of metallicities photoionized by radiation from OB associations with a range of ages. Similarly, Seyferts and LINERs form a sequence that matches gas which is photoionized by a power law spectrum with a range of intensities; the highest excitation Seyferts correspond to the most intense nuclear radiation field. The apparent continuity of Seyferts and LINERs on these diagrams supports the possibility that at least some LINERs are simply low intensity Seyferts.

Turning now to radio properties, Seyferts belong to the majority ($\sim$ 90%) of AGN in being *radio quiet*—more luminous than normal galaxies but $\sim 10^3$–10^4 times fainter than radio-loud AGN. The closest radio-loud counterparts to Seyferts have similar optical luminosity and are called Broad Line Radio Galaxies (BLRG) and Narrow Line Radio Galaxies (NLRG), with optical spectra very similar (though not identical) to Seyfert 1s and Seyfert 2s respectively. At higher optical luminosity, we have radio-loud quasars, and at lower optical luminosity we have radio galaxies whose spectra are often LINER-like. Although most radio galaxies have huge radio sources which extend well outside the host galaxy, some have much smaller radio sources comparable in size to, though much more powerful than, the Seyfert sources (these are called, depending on details, Compact Steep Spectrum (CSS), Compact Double (CD) or Gigahertz Peaked Spectrum (GPS) sources). It is quite likely that similar physical phenomena are occurring in the Seyferts and these compact powerful sources—both are embedded in a dense gaseous environment and probably interacting strongly with it. Thus, studying one may help understand the other.

The fundamental reason why $\sim$ 5–10% of AGN become radio-loud is still not understood, though it is probably related in some way to the interesting fact that radio-loud and radio-quiet AGN tend to inhabit different types of host galaxy: ELLIPTICAL and SPIRAL GALAXIES respectively. It has been suggested that the radio-loud AGN have rapidly spinning (Kerr) BLACK HOLES which drive powerful jets along the spin axis, and these jets generate the powerful radio source. Conversely, slowly rotating (Schwarzschild) black holes cannot drive such jets and so remain radio-weak. The link between black hole spin and host galaxy type could arise from the fact that the elliptical hosts have formed from the merger of two spirals along with the merger of their two black holes to form a single rapidly rotating black hole.

Finally, Seyferts have little relation to the highly variable 'BLAZAR' classes of AGN: BL Lac objects, OVV (optically violently variable) quasars and HPQs (high polarization quasars). These are all radio-loud objects and, under the unified scheme for this category, are thought to be seen looking directly down a powerful jet where relativistic Doppler boosting enhances the luminosity, variability and polarization of the continuum.

Black holes and continuum emission

It is worth noting that the evidence for black holes in Seyferts and other AGN is mostly indirect: large variable luminosity; relativistic jets with a stable axis; high energy spectra. Ideally, one would study gravitational dynamics of near-nuclear stars or gas. While this has been possible in a number of normal or weakly active galaxies, it is very difficult for most Seyferts simply because of the bright nuclear light and uncertain nature of the gas motions. With many ongoing HST observations, the case is now building for black holes at the centers of most (perhaps all) luminous galaxies, with black hole mass a few per cent of the bulge mass. It would be ironic if the discovery of black holes in most normal galaxies gave the most convincing evidence, by continuity, for their presence in AGN.

Two methods might provide a better approach to detecting black holes in Seyferts. The first method is to measure the dynamics of water masers in the dense warm gas close to the center. The classic case is NGC 4258 (not, in fact, a Seyfert galaxy), which provides the best case to date for a supermassive black hole, but other possible examples are increasing in number. The second method is to study the Fe Kα x-ray emission line profile at 6.4 keV. In several cases it is very broad and double peaked, suggesting its origin in a nuclear accretion disk at a few tens of Schwarzschild radii. An important goal will be to use profile fits to infer not only the mass of the hole but also its spin and orientation.

The energy released from matter falling towards the central black hole emerges in both bulk flows and photons; the latter yields, either directly or indirectly, the observed nuclear continuum emission. Perhaps the most noteworthy aspect of AGN continua is their extremely wide spectral range, with approximately equal energy per decade of frequency from far infrared to 100 keV x-rays (five decades) with extensions to radio and γ-ray energies in about 10% of AGN (not usually Seyferts). To a first approximation, the continuum shape can be described as a power law, $f_\nu \propto \nu^{-\alpha}$, with index $\alpha \sim 0$–1, with several features superposed. These features include: (a) a 'Big Blue Bump' (BBB) comprising a rise below $\sim$ 4000 Å peaking in the UV or (unobservable) EUV and dropping to rejoin the underlying continuum in the soft ($\sim$ 0.5 keV) x-ray region (the 'soft excess'); (b) an infrared peak rising from ~ 1 μm, peaking at $\sim$ 25–60 μm and falling again at $\sim$ 0.3 mm; (c) a rise at the highest energies $\sim$ 5–200 keV with cut-off at even higher energies.

The interpretation of these various components is still somewhat uncertain, though there seems to be a general consensus. The underlying power law might be generated by the synchrotron self-Compton process: a population of relativistic electrons not only generates low energy photons via the synchrotron process but then inverse-Compton scatters these same photons up to higher energies. A related model for the x-ray power law involves inverse-Compton scattering of optical–UV photons produced in the ACCRETION DISK by electrons in a hot corona above the disk. The BBB is thought to arise from thermal emission from the accretion disk, with progressively higher energy photons coming from higher temperatures at smaller radii. Although the overall BBB feature can be nicely fitted by disk models, some expected disk signatures are *not* seen: a strong Lyman edge at 912 Å; high polarization; and significant phase delays between flux variations at different wavelengths. For this reason alternatives have been suggested, such as an optically thin bremsstrahlung component. The infrared peak, which can be very strong in some objects (e.g. NGC 1068), is thought to arise in most cases from thermal emission from dust. The rise longward of ~ 1 μm suggests hot dust close to its sublimation temperature at $\sim$ 2000 K, possibly located within $\sim$ 1 pc. At longer wavelengths ($\sim$ 25–60 μm) the dust is cooler and probably located in or near the NLR. Finally, the x-ray rise might come from reflection of the underlying power law off 'cool' gas, either the accretion disk or the dense obscuring torus. A byproduct of such reflection is fluorescence of the Fe Kα emission line at $\sim$ 6.4 keV, which can be quite strong.

The observed blue–UV continuum in Seyfert 2s deserves further comment since, as we have discussed, the nuclear contribution should be hidden behind an obscuring torus. Why, then, do many Seyfert 2s have a sufficiently strong UV excess to show up in the Markarian survey? The reason is that much of the blue–UV light in Seyfert 2s is *extended*, coming from the inner few kpc. The origin of this continuum is still under some debate, but it seems there are at least several contributions. Polarization observations indicate that part of the emission is scattered from the hidden nucleus. The remainder (sometimes called 'FC2', for Featureless Continuum 2) may be a combination of near-nuclear star formation, Balmer continuum emission from the ionized gas, and continuum emission from hot post-shock gas associated with the radio source.

Broad line region

A defining characteristic of Seyfert 1 spectra is the presence of broad emission lines, including the Balmer lines, He II λ4686 and He I λ5876 in the optical, and Lyα λ1212, C IV λ1549, C III] λ1909 and Mg II λ2800 in the near UV. In the early 1980s it was found that the Balmer line strengths in Seyferts and quasars form a single tight correlation with the non-stellar continuum strength, confirming a basic connection between the two: continuum emission photoionizes the BLR gas which then produces line radiation. An estimate of the gas density in the BLR comes from the absence of any broad components on the forbidden lines. These so-called 'forbidden' emission lines come from electron transitions which cannot occur via the fast electric dipole mode (which requires a quantum number change $\Delta l = \pm 1$). With only slower modes of transition available (e.g. magnetic dipole), the ions are vulnerable to collisional deexcitation in a high density gas where the mean time between collisions is small. The 'critical density', $n_{\rm crit}$, above which collisional de-excitation becomes important varies widely for different lines, so one can bracket the gas density in the BLR by noting which lines have broad components and which do not. For example, while the [OIII] λ4363 line with $n_{\rm crit} \sim 3 \times 10^7$ cm^{-3} has no broad component the semiforbidden CIII] λ1909 line with $n_{\rm crit} \sim 3 \times 10^{10}$ cm^{-3} does, implying a gas density in the BLR somewhere in the range $10^{7.5}$–$10^{10.5}$ cm^{-3} (see below for a refinement of this estimate). In contrast to the forbidden lines, the so-called 'permitted' lines arise from fast ($\sim 10^{-8}$ s) electric dipole transitions with correspondingly high critical densities $\sim 10^{17}$ cm^{-3}. Such lines, which include those due to recombination, are therefore easily produced in the BLR gas.

In the last decade, Seyfert variability studies have significantly helped develop our picture of the BLR. In these studies, the emission lines and continuum are repeatedly measured over periods of many months. Because of the finite size of the region, it takes time for a change in the central continuum brightness to reach the BLR gas and thereby cause a change in the emission line. Allowing for light travel delays between the continuum source and BLR gas and between the BLR gas and us, it is in principle possible to reconstruct the distribution of line emission and velocity field throughout the BLR. In practice, this full 'reverberation mapping' has not yet been possible, but instead simple time delays have been measured in the response of each emission line to the continuum, and these delays indicate an approximate region size. The most well studied object is the Seyfert

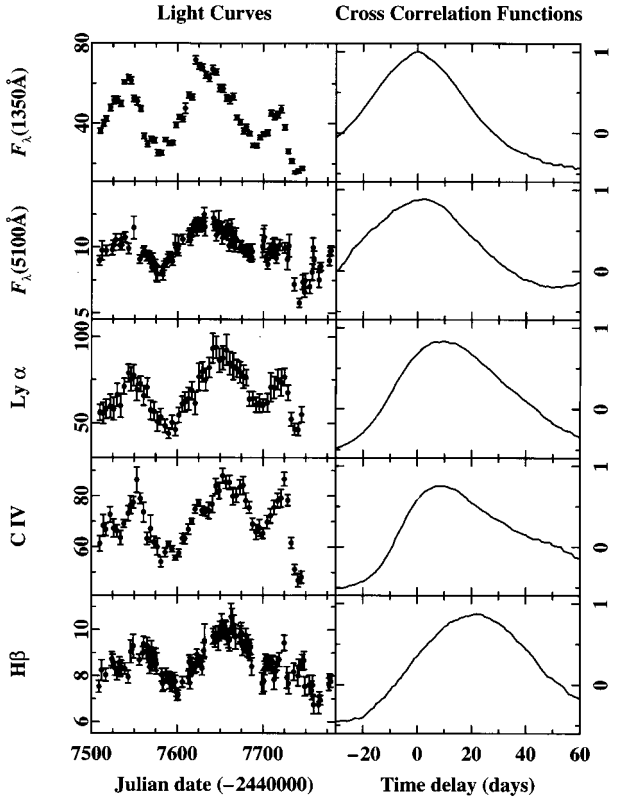

Figure 5. Variability in NGC 5548 over a period of 280 days in 1988–89. Left panels show changing fluxes in the continuum (upper two) and emission lines (lower three), while the right panels show the cross correlation of each flux curve with the UV continuum (uppermost left panel). Note that while the optical and UV continua vary together, the Lyα, C IV λ1550 and Hβ emission lines lag behind by increasing amounts, Hβ being delayed by about 20 days. These lags indicate the size of the BLR (about 20 light days) and the fact that it is radially stratified, with C IV produced preferentially at smaller radii and Hβ at larger radii. (Taken from Peterson B M 1997 *An Introduction to Active Galactic Nuclei* (Cambridge University Press), figure 5.6, p 86).

1.5 galaxy NGC 5548, for which delays of $\sim$ 2–10 days are found for the highest ionization lines (e.g. He II λ1640, C IV λ1549) and $\sim$ 10–20 days for the lower ionization lines (e.g. Lyα, Hα, Hβ, CIII] λ1909), indicating a radially stratified BLR with size $\sim$ 2–20 light days (figure 5). Surprisingly, these size estimates were a factor of ten smaller than previous estimates based on photoionization calculations (see below). The reason for the discrepancy is now understood: not only does stratification undermine the simple photoionization estimate but the densities in the BLR are probably higher than previously thought (e.g. $\sim 10^{11}$ cm^{-3} in the C IV λ1459 emitting region).

Since the ionization structure in the BLR is roughly the same from object to object (because the line ratios are similar), we infer that BLR sizes must increase for more luminous objects. Using the C IV λ1549 data from NGC 5548 as fiducial, the form of the dependence is $R_{\rm BLR} \sim 10 h_0 L_\lambda(1350\ \text{Å}, 40)^{1/2}$ light days, where h_0 is the Hubble constant in units of 100 km s^{-1} Mpc^{-1} and $L_\lambda(1350\ \text{Å}, 40)$ is the continuum luminosity at 1350 Å in units of 10^{40} erg s^{-1} Å^{-1}. Since, roughly speaking, quasars are $\sim$ 100 times more luminous than Seyferts, they have BLRs which are $\sim$ 10 times larger, perhaps a few light months to a light year across.

In the 1980s photoionization models were developed which aimed to reproduce the observed emission line strengths. In general, these calculations consider a power law (or AGN-like) continuum impinging on a thick slab of gas. At a given depth in the cloud, ionization and thermal equilibrium conditions are evaluated, together with the emitted line spectrum. Absorption of the incoming ionizing continuum is calculated and the modified continuum enters the next zone deeper in the cloud. The calculation repeats for ever deeper zones in the cloud until the gas is sufficiently cool and/or neutral that no more emission is produced. Overall, the ionization degree drops into the cloud, becoming suddenly more neutral at a depth corresponding to the classical Strömgren depth (where the total number of ionizing photons is balanced by the total number of hydrogen recombinations). However, unlike H II regions ionized by hot stars, AGN continua also have a high energy component which penetrates beyond the Strömgren depth to create an extended partially ionized zone in which many low ionization lines are produced. Usually, the emergent spectrum from a single cloud is compared to observations, though more recently cloud ensembles spanning a range of conditions have been considered in an attempt to match the stratified nature of the BLR.

Several parameters help define these photoionization calculations. The most important is the 'radiation parameter', defined as the ratio at the cloud front of the ionizing photon density to the hydrogen density: $U = N_{\rm ion}/n_{\rm H}$, where $N_{\rm ion} = Q/4\pi r^2 c$ where Q is the number of ionizing photons produced by the central source per second, and r is the distance to the cloud. Other relevant parameters are gas density, cloud thickness, ionizing spectral shape and element abundances. Optimum fits suggest that for Seyfert 1s, $U \sim 0.04$ and $n_{\rm H} \sim 10^{11}$ cm^{-3}. Estimating cloud thickness is more difficult. The fact that in variable objects the emission lines follow the continuum tells us the clouds are at least optically thick to the ionizing radiation, i.e. they are at least thicker than the Strömgren depth $S \sim Uc/n_{\rm e}\alpha_{\rm B} \sim 5 \times 10^{10}$ cm where $n_{\rm e}$ is the electron density and $\alpha_{\rm B}$ is the case-B hydrogen recombination coefficient ($\sim 2.5 \times 10^{-13}$ cm^3 s^{-1}). Matching the low ionization strengths requires the extended partially ionized region to be a few times deeper—perhaps a few times the diameter of our Sun. There is also evidence, it should be said, for an optically thin component to the BLR gas, coming from studies of line ratio and profile variability.

It is possible to estimate some other properties of the BLR line-emitting gas, starting with the basic equation for the production of Hβ by recombination: $L_{\rm H\beta} =$

$h\nu_{H\beta} n_e n_H \alpha_{H\beta} V$ where $h\nu_{H\beta}$ is the energy of each Hβ photon, n_e and n_H are the electon and proton densities, V is the volume of ionized gas, and $\alpha_{H\beta}$ is the recombination coefficient for Hβ ($\sim 3 \times 10^{-14}$ cm^3 s^{-1}). Since the mass of ionized gas is simply $M = m_p n_H V$ where m_p is the proton mass, we find an ionized gas mass and volume of $\sim 0.1\, M_\odot$ and 10^{45} cm^3 for a typical Hβ luminosity $\sim 10^{42}$ erg s^{-1} and BLR gas density $\sim 10^{11}$ cm^{-3}. Taking the BLR radius of 10 light days from the variability measurements given above, we find that the ionized gas occupies only $f_c \sim 1.5 \times 10^{-5}$ of the BLR volume (f_c is called the filling factor). If we assume the gas is in the form of clouds with diameters a few times the Strömgren depth ($d_c \sim 5 \times 10^{11}$ cm) we derive a number of clouds $N_c \sim V/d_c^3 \sim 10^{10}$ which collectively intercept a fraction of the central radiation of $C_c \sim N_c d_c^2/4\pi r^2 \sim 0.3$ (C_c is called the covering factor). In this picture, then, the BLR is sparsely filled by a large number of small clouds which collectively intercept $\sim 30\%$ of the ionizing radiation.

The velocity field in the BLR is poorly understood, despite the fact that the emission line profiles clearly have Doppler origin. Profiles have approximately logarithmic form (flux $\propto \log \Delta\lambda$) often with slight asymmetry and/or substructure, with full widths at half maximum (FWHM) anywhere from 1000 to 10 000 km s^{-1} and maximum wing widths of up to 30 000 km s^{-1}. Lines in the same object can have slightly different shape (e.g. He II λ4686 is often broader than Hβ), indicating both velocity and ionization stratification in the BLR, with higher velocities at smaller radii. One approach has been to fit each line by the sum of two components, one broad and one very broad with possible blueshift. These fits support the decrease in velocity for lower ionization gas, and point to a slight radial velocity component, although profile variability studies suggest that radial flow is *not* a dominant component of the velocity field. If the velocities are gravitational, estimates of central mass $M \sim rv^2/G \sim 10^7$–$10^8\, M_\odot$ with some evidence for a correlation between central mass and luminosity. The luminosities derived amount to $\sim 1\%$ of the Eddington luminosity, which is the natural upper limit to accretion-powered energy release when outward radiation pressure just balances inward gravitational force, limiting further accretion.

The geometry of the BLR is also poorly understood, with spherical or flattened cloud distributions as obvious possibilities, including a thin but flared disk, although the absence of very narrow lines expected for face-on disks weighs against this last possibility. The origin and evolution of the cloud system are also poorly understood. Possibilities that have been explored include a two-phase medium in which the clouds are in pressure balance with a hot intercloud medium; clouds may be confined by magnetic forces; clouds may form in cooling post-shocked gas; clouds may even comprise the extended atmospheres of giant stars. Each of these has its strengths and weaknesses, and we must await further work to clarify the true situation.

Narrow line region

In the spectra of Seyferts, the narrow forbidden and permitted emission lines come from a region well outside the BLR, spanning a few tens of pc to a few kpc called the 'Narrow Line Region' (NLR). Unlike the BLR, therefore, ground-based telescopes can often resolve the outer parts of the NLR while HST has provided some detailed images and spectra. The mere presence of forbidden lines tells us that gas densities are lower than in the BLR. At these lower densities the physics of line production is simpler and line ratios may be used to estimate physical properties of the ionized gas. Classic examples include the two line ratios: [S II] $\lambda\lambda$6717/6731 and [O III] $\lambda\lambda$5007/4363 which yield electron densities $\sim 10^3$–10^4 cm^{-3} and electron temperatures $\sim$ 1–2 $\times 10^4$ K respectively. Such simple estimates must be viewed with caution, however, because they represent weighted averages over a wide range of conditions: for example, gas densities probably rise from $\sim 10^2$ cm^{-3} on kpc scales to $\sim 10^{6-8}$ cm^{-3} in the inner regions. More sophisticated approaches follow the same strategy as for the BLR: photoionization calculations evaluate conditions within a single gas cloud and, in more recent work, integrate over a distribution of cloud properties. As with the BLR gas, much of the NLR gas is thought to be optically thick to the ionizing radiation, although studies of the He II λ4686/Hβ ratio indicate the presence of some optically thin gas. In trying to match these calculations to observations, sequences of models are evaluated with a range of radiation parameter and/or relative mix of optically thick to optically thin gas. Typical values for the radiation parameter found for the NLR are $U \sim 0.01$, with some evidence for higher values in Seyfert 1s than Seyfert 2s.

Repeating the analysis for the BLR, we can derive crude estimates for the global properties of the NLR gas. Taking as fiducial, $L_{H\beta} \sim 10^{41}$ erg s^{-1}, a gas density of $\sim 10^3$ cm^{-3} and NLR size of ~ 100 pc, we obtain a mass of ionized gas of $\sim 10^7\, M_\odot$ with filling factor $\sim 10^{-2}$. The Strömgren depth in the clouds is $\sim 10^{18}$ cm; there are $\sim 10^6$ clouds with integrated covering factor ~ 1. While the numbers are far from precise, they do indicate that the amount of gas is dynamically unimportant, that it only sparsely fills the region, and that it intercepts a significant fraction of the ionizing radiation.

As the name suggests, the emission lines from the NLR have 'narrow' Doppler widths, with FWHM $\sim$ 200–800 km s^{-1} (a few lie outside this range). The emission line shapes are almost always more peaky than Gaussian, and most have an asymmetry with the base and wing stronger and more extended on the blue side than the red (figure 6). This asymmetry tells us that, at least for the higher velocity, more nuclear gas, there is a radial flow and part of the region is obscured by dust. If the far side of the region is obscured by intervening dust, then the flow is *outwards* (the visible near side is blueshifted). If the clouds themselves contain dust, and the line emission comes from the side of the cloud facing the central source, then the flow is *inwards* (we cannot see the clouds on the near side

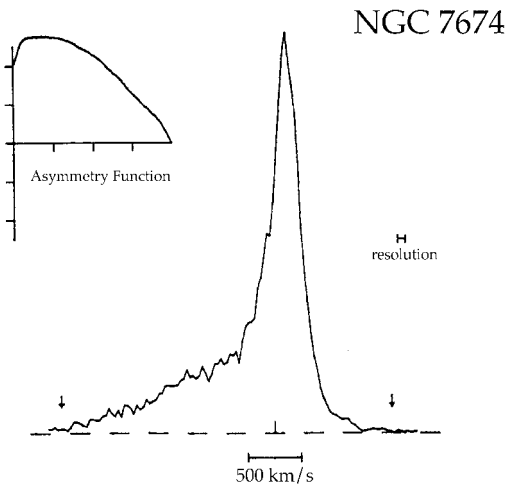

Figure 6. The [O III] λ5007 emission line profile from the nuclear region of NGC 7674 provides an extreme example of an asymmetric blue wing. A velocity scale, line median, instrument resolution and asymmetry function are also shown.

since we look into their backs). Recent observations have shown that the optical and infrared forbidden lines have similar asymmetries, showing that the dust is still opaque even at these long wavelengths. The preferred scenario is thick nuclear dust, possibly in a dense disk, blocking the far side and indicating an outflow. The outflow might be driven by a nuclear wind or be related to the jets which give rise to the radio source. For those Seyferts with relatively strong double or triple structured radio sources it is often possible to see separate red- and blueshifted emission components close to the radio lobes, indicating bipolar driven outflows. In these objects, the integrated line profile can be particularly structured and broad, with base and core widths up to $\sim$ 1000 km s^{-1} (examples include NGC 1068, MKN 3, MKN 78). For most objects, however, there is good evidence that the majority of the NLR gas, as measured by the [O III] λ5007 profile core width (FWHM), is moving in the gravitational field of the bulge of the host galaxy. The evidence includes the fact that the profile peaks and cores are close to the rest frame of the galaxy, and that there are good correlations of the [O III] λ5007 emission line width with (a) rotation velocity of the galaxy, (b) bulge luminosity and (c) bulge stellar velocity dispersion. Stated simply, galaxies with massive bulges have relatively broad forbidden lines (e.g. $\sim$ 500 km s^{-1}), while galaxies with low mass bulges have relatively narrow forbidden lines (e.g. $\sim$ 200 km s^{-1}). Galaxies with relatively strong double or triple radio sources tend to stand off these correlations with yet broader lines, due to bipolar flows. For the gravitationally dominated gas, it is still unclear whether the predominant motion is rotation or random, though probably both occur.

Not all emission lines have the same profile shape, and in general lines of higher ionization and/or higher critical density tend to be broader with a higher degree of asymmetry. This indicates that, like the BLR, the NLR is stratified with the higher velocity, more nuclear gas having higher density and ionization degree. It is conceivable, though not yet shown convincingly, that a continuous sequence of conditions connects the inner NLR to the BLR.

The spatial structure of the NLR emission has been studied using emission line imaging, both from the ground and using HST. In this technique, images are taken through two narrow pass filters, one centered on the color of the emission line (ON band) and one centered on the nearby continuum (OFF band). By subtracting the OFF band from the ON band one is left with a pure emission line image. Furthermore, by dividing two emission line images such as [O III] λ5007 and Hβ one can generate a map of the gas excitation which clearly highlights AGN-related emission ([O III]/Hβ $\sim$ 10) and distinguishes it from star formation emission ([O III]/Hβ $<$ 3). Such images indicate that the NLR is often elongated, with an axis parallel to the radio axis. Indeed, for those Seyferts with well developed radio sources the NLR emission is closely related to the radio source, with brighter emission either coincident with jets and jet bends, or surrounding and sheathing radio lobes, sometimes with a curved 'bow shock' appearance. Spectroscopic studies show higher velocities for this radio-related emission, indicating strong dynamical interaction and an overall bipolar outflow, but also including split lines near jets, possibly indicating lateral expansion away from the jet. A good example of close radio/emission line association is Markarian 78 (figure 7).

The close association between line and radio emission in the NLR raises the important possibility that the gas is ionized, at least in part, by shocks arising in the interaction. Although early calculations of slow shocks could only match LINER-like spectra, more recent calculations of fast ($\sim$ 500 km s^{-1}) shocks can match Seyfert-like spectra. A key feature of these calculations is the production of UV and x-ray radiation, both line and continuum, in the hot post-shock gas. This radiation then photoionizes gas both behind the shock and in front of it, yielding a spectrum quite similar to that observed in Seyferts. At present, 'photoionizing shocks' and standard power law photoionization (possibly including optically thin gas) give an equivalently good match at least to the optical lines, though there is some hope that UV lines will help discriminate between the models, as long as the uncertainties introduced by dust reddening are not too great.

Returning to the emission line images and excitation maps, a number show sharp edges which outline parts of a cone, or bi-cone if it occurs on both sides. As described earlier, this seems to indicate a partly shadowed nuclear source of ionizing radiation. These emission regions can extend out to considerable distances, $\sim$ 15–20 kpc, where they are termed the 'Extended Narrow Line Region' or ENLR. This emission has high excitation and narrow lines of low velocity, suggesting it is simply undisturbed ambient gas residing either in the disk of the galaxy or in the galactic environment. The fact that most

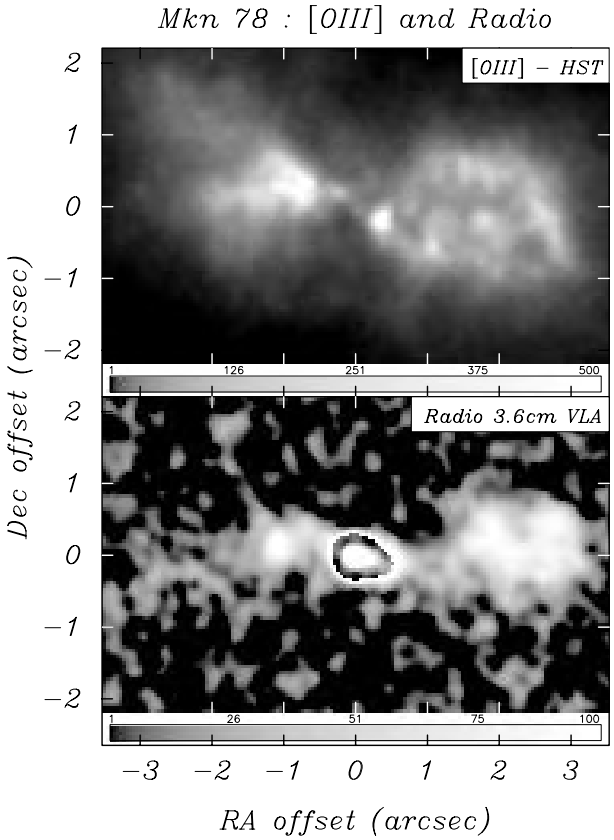

Figure 7. HST [O III] emission line image and VLA radio image of the Seyfert 2 galaxy Mkn 78 showing close spatial association. Note that a dust lane crosses the nucleus, hiding the most nuclear [O III] emission. Gray scale numbers are proportional to flux, with the radio core rescaled by a factor of five for clarity. For this galaxy 1 arcsec $\sim$ 1 kpc ($h_0 = 50$ km s^{-1} Mpc^{-1}). (Data courtesy of M Whittle and A S Wilson.)

ENLRs lie well beyond any radio source and can show conical form suggests they are ionized by the central UV radiation source. Recently, however, careful estimates of the required UV flux suggest that at larger radii there may be an additional source of ionization, though what this is is not yet known.

A final pragmatic theme is the frequent need to correct measured spectra for the effects of reddening by dust. Fortunately, the NLR Balmer line strengths are expected to be close to their theoretical values, and so any deviation can be attributed to reddening. For example, the Hα/Hβ flux ratio should be $\sim$ 2.8 (the 'Case B' value, though a more detailed calculation gives 3.1) and so a measured value of, say, R, yields an estimate for the absorption due to dust of $A_V \simeq 6.8 \log_{10}(R/2.8)$ magnitudes in the V band, where the coefficient depends on the reddening law (Whitford's law in this case). Knowing A_V allows one to correct the observed spectrum, using the same reddening law $f(\lambda)$, where $A_\lambda = A_V \times f(\lambda)$.

Hosts, environment and triggering

While the previous sections have concentrated on the anatomy of activity in Seyfert galaxies, there remains an important question: why are some galaxies active while others are not? Although we cannot yet answer this question with confidence, two or three lines of enquiry help pave the way forward. The first is to ask whether Seyfert host galaxies are unusual in any way; the second is to ask whether any active properties correlate with any host galaxy properties; and the third is to identify mechanisms which might send gas down to fuel the nuclear regions. In this area, empirical studies are difficult because of the statistical weakness of the effects and the presence of sample and control biases.

Perhaps the one clear result concerns the morphological type of the host galaxies: Seyferts favor early-type spirals, S0–Sbc, clearly avoiding late-type spirals and, to a lesser extent, ellipticals. Interestingly, LINERs show a similar distribution (with somewhat more ellipticals), while radio galaxies are almost exclusively elliptical or S0. In all these cases, more luminous galaxies are more likely to be active. It seems, therefore, that an important condition for the onset of activity is a relatively massive bulge. There is also a tendency for active galaxies to be disturbed in some way and/or have a nearby companion—both being conditions which may lead to nuclear fueling. The neutral gas content (atomic and molecular) of Seyferts is basically normal, though Seyfert 2s may have more molecular gas and associated star formation than otherwise similar non-active galaxies. Recent HST images have also shown that Seyfert 2s tend to inhabit later Hubble types and have more nuclear dust lanes than Seyfert 1s. This suggests a modification to the standard unification scheme: Seyfert 2s simply have more nuclear dust than the Seyfert 1s and are therefore more likely to be obscured, rather than being identical except for our viewing angle.

It is worth noting a few active properties which do (or don't) correlate with host galaxy properties. First is the axis of nuclear activity, as defined by the radiation field and/or radio source. Overall, there appears to be little alignment of this axis with the large scale disk or bar of the host galaxy. Recent evidence, however, suggests that for later Hubble types there *is* an alignment with the host disk, while for early Hubble types the alignment is with smaller scale nuclear gas or dust disks or lanes whose more random orientation probably reflects recent merger or infall history. Because the NLR resides within the galaxy bulge, it is perhaps not surprising that some NLR properties correlate with bulge luminosity, for example emission line and radio luminosities. The origin of these correlations is not yet clear, but might involve a number of properties which depend on bulge mass (i.e. depth of gravitational potential): emission region volume, gas and radio source pressures, mass loss rate from bulge stars, and mass of central black hole. More easy to understand is the dependence of NLR emission line width on bulge mass, since the gas velocities are largely gravitational. An interesting wrinkle on this last result is

that disturbed galaxies have even broader emission lines, confirming that such disturbances can affect gas motions in the inner regions. Perhaps more fundamental is a possible correlation between nuclear (active) luminosity and host galaxy (or more likely, bulge) luminosity—low luminosity Seyferts reside in lower mass bulges than quasars. An obvious explanation is that more massive bulges have more massive central black holes, a result supported at least in part by recent black hole mass measurements in more normal galaxies.

Perhaps the central theoretical problem has been to understand how gas moves from far out in the galaxy disk down to the innermost regions where it can accrete onto the black hole—a loss in ANGULAR MOMENTUM by a factor $\sim 10^5$! Early work focused on bars as a means of draining angular momentum from gas, via shocks and dissipation. It is at present unclear how important this particular mechanism is since, although studies have been somewhat ambiguous, there seems to be no tendency for active nuclei to prefer barred galaxies. More recently, Barnes and Hernquist have shown, using computer simulations, that galaxy encounters and mergers can be particularly effective at sending gas into the nuclear regions. The tidal fields resulting from the encounter help create a gaseous bar which lags behind a stellar bar. The gravitational torque on the gas robs it of angular momentum and it falls inwards, losing up to $\sim 99\%$ of its angular momentum. At smaller radii it is unclear what happens: gas may build up and become unstable to self gravity and/or there may be bars within bars which help funnel the gas to ever smaller radii. Once in an accretion disk, however, Balbus and Hawley have shown that magnetically driven turbulence provides enough viscosity to drive the gas inwards to the black hole.

The future

We now briefly identify several themes likely to be pursued in the coming years. (a) The hunt for black holes will continue, aiming to establish a demographic perspective—how do black hole mass and spin relate to AGN or host properties? (b) How does the inner accretion disk function, and how does it play a role in generating the continuum emission? (c) Much remains to be done to find out the structure and velocity field of the BLR—ideally, its kinematics will be dominated by black hole gravity giving another handle on the properties of the central object. (d) The root cause of the apparent unification of Seyfert 1s and 2s needs to be clarified—is the torus model too simple in the light of the recent HST observations showing more distributed dust lanes in Seyfert 2s? (e) We need to refine our picture of the NLR, and in particular the importance of the radio emitting jets—clearly the jets accelerate the gas, but do they also ionize it? (f) What is the nature of the extended UV continuum in Seyfert 2s, and is enhanced star formation associated with nuclear activity? (g) Finally, we would like to know how activity is triggered in more detail. Although interactions are now known to send gas to the central kpc, how does it get from there to the pc scale and beyond?

Clearly, these are exciting times in the study of Seyferts.

Shanghai Astronomical Observatory

The Shanghai Astronomical Observatory, Chinese Academy of Sciences (CAS), is located in Shanghai, China. It was established in 1962 combining Xujiahui and Sheshan, which were founded in 1872 and 1900 respectively. The main fields cover astrophysics and astrogeodynamics, including star clusters, our Galaxy, galaxies, Earth rotation and satellite dynamics application. The major facilities are: 1.56 m telescope, 25 m radio telescope, 60 cm SLR system and 40 cm astrograph. The staff consists of some 50 astronomers, 40 engineers and technicians.

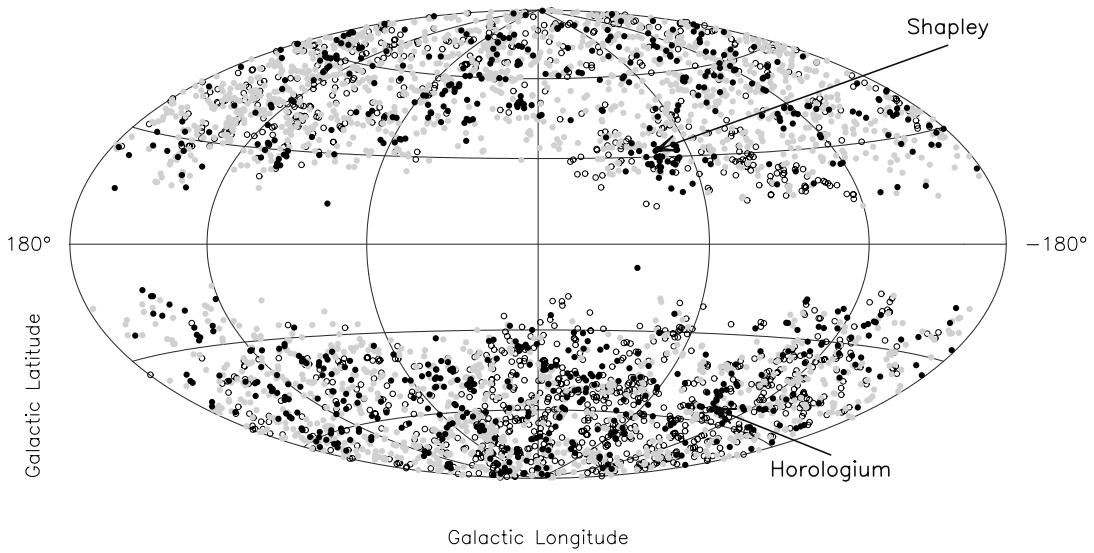

Figure 2. The distribution of 4076 optically selected Abell clusters plotted in an equal-area projection in Galactic coordinates. Clusters lying within redshift $z \leq 0.1$ are plotted in black, between $0.1 < z \leq 0.2$ in grey and those with $z > 0.2$ as open circles. The underpopulated area is the portion of the sky obscured by our own Galaxy. The two richest concentrations of clusters in the $z \leq 0.1$ universe are indicated.

Is it the 'Great Attractor'?

Several studies of the distances and motions of galaxies have revealed large systematic departures from the Hubble Flow in the nearby universe. Many attempts have been made to account for them in terms of the gravitational effects of significant overdensities and underdensities in the local distribution of matter.

The simplest such model is that of the 'Great Attractor', originally proposed to be a large concentration of galaxies of mass about $2 \times 10^{16}\, h^{-1}\, M_{\odot}$, situated at a distance of $r_{\rm GA} = 42\, h^{-1}$ Mpc from us. Subsequent studies have disagreed on whether a back-flow beyond $r_{\rm GA}$, which should be the signature of a single mass concentration causing our peculiar motion, is detected or not. Interestingly, the detailed reconstruction of the density field from peculiar velocities, within $50\, h^{-1}$ Mpc from us, finds evidence for a large concentration of mass at the distance of the proposed Great Attractor.

However, it is uncertain whether this concentration is enough to account for the peculiar velocities in the Local Supercluster, and whether the peculiar velocities converge on larger scales (see also SUPERCLUSTERS AND THE LOCAL SUPERCLUSTER). It is in this context that the Shapley concentration was rediscovered in the 1980s.

The fact that the Shapley concentration lies within 10° of the direction of motion of the Local Group, and very close to the proposed position of the Great Attractor, prompts us to consider the possibility of its being an important contributor to the peculiar motion of the Local Group. However, the Shapley concentration is situated at three times the putative distance of the Great Attractor. If it were to be responsible for the entire peculiar motion of the Local Group (600 km s^{-1} towards Hydra–Centaurus), it would have to have a mass of $M_{\rm GA} \sim 2.6 \times 10^{17}\, h^{-1}\, M_{\odot}$.

If all the galaxies brighter than 17th magnitude within 10° ($25\, h^{-1}$ Mpc) of Shapley 8 were placed at a distance of $140\, h^{-1}$ Mpc, the mean distance of the Shapley concentration, then the total blue light from these galaxies would amount to $L_B \sim 5 \times 10^{13}\, h^{-2}\, L_{B,\odot}$. This is clearly an overestimate, because a lot of these galaxies would be in the foreground, particularly in clusters belonging to the Hydra–Centaurus supercluster. So the *lower limit* to the mass-to-light ratio of the Shapley concentration would be $M/L_B \sim 4500\, h$, if it alone were responsible for the entire peculiar motion of the Local Group. This is an improbably high value, considering that a large spiral galaxy like ours has a mass-to-light ratio of about 10, and a typical cluster of galaxies has $M/L_B \sim 300\, h$. Indeed, for a critical-density universe ($\Omega_0 = 1$), the corresponding value is $M/L_B \sim 1500\, h$.

The optical dipole

Both gravity and luminosity decrease as the inverse square of the distance. Thus the dipole moment of an all-sky distribution of galaxies (individually weighted by their luminosities) can be used to estimate the peculiar acceleration of the Local Group. Since this does not require one to know the distances of individual galaxies, it can be calculated from a catalog of positions and luminosities (or sizes) of galaxies. It has been shown that the net acceleration of the Local Group estimated in this way is almost parallel to its direction of motion, supporting the notion that in the universe the distribution of matter follows the distribution of light.

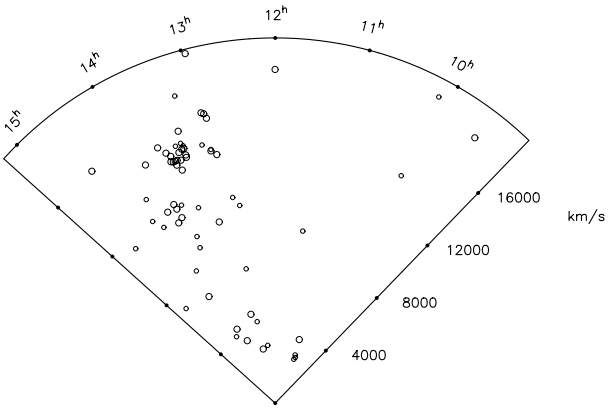

Figure 3. Galaxy clusters with known redshift in the direction of the motion of the Local Group (in a wedge of width 30° in declination). Rich clusters are plotted as larger circles, and poor clusters and groups as smaller ones. This plot of their position on the sky (right ascension) against mean redshift shows the existence of three distinct groups of clusters. The poorer clusters < 5000 km s^{-1} belong to the 'Hydra–Centaurus Supercluster'. The dense bunch of clusters at $\sim 14\,000$ km s^{-1}, between $13^{\rm h}$–$14^{\rm h}$, consisting of significantly richer clusters, is the 'Shapley Concentration'. The Abell 3571 group of clusters at $\sim 12\,000$ km s^{-1} belongs to a foreground filament-like structure.

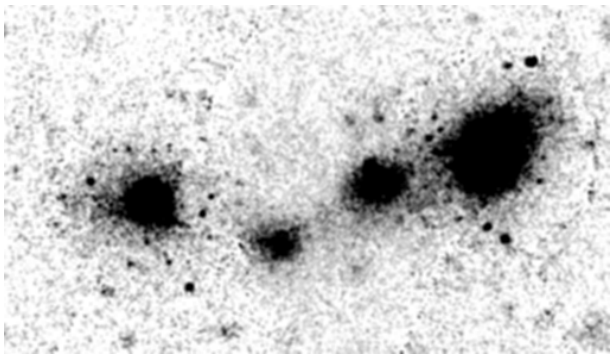

Figure 4. An x-ray map of the core of the Shapley concentration, from a mosaic of two long observations with the ROSAT PSPC. The cast of characters, from left to right, are the clusters Abell 3562, SC1329-31, SC1327-31 and Abell 3558 (Shapley 8). All of these clusters are around a redshift of 14 000 km s^{-1}. Shapley 8 is the central cluster of the Shapley concentration, and it is almost certain that the other three clusters are in the process of merging with it.

However, for galaxies in an extended region towards the direction of the motion of the Local Group, which includes the Shapley concentration, all galaxies smaller than the mean size of galaxies at about $45\,h^{-1}$ Mpc contribute only about 15% of the dipole acceleration due to those that are larger (nearer).

Its contribution to our peculiar motion

Both the values of the luminosity and the optical dipole of the Shapley concentration indicate that it could be responsible for 10–15% of the net acceleration of the Local Group, the rest being due to much nearer galaxies. This is consistent with the sum of the masses of its component clusters found from x-ray analyses.

If the Shapley concentration were a major source of the dipole acceleration of the Local Group, one would expect peculiar velocities to continue to rise beyond the nearer concentration of galaxies. At this moment there is conflicting evidence about whether this is seen or not.

This makes the Shapley concentration unlikely to be the Great Attractor, since that would imply (a) that mass does not follow light, and dark matter prefers to reside in clusters and superclusters of galaxies than in the field, and (b) that superclusters are capable of having higher mass-to-light ratios ($M/L_B \gtrsim 4000\,h$) than even the richest clusters of galaxies (e.g. for the Perseus cluster: $M/L_B \sim 350\,h$), over much larger scales. Both of these are against theories of GALAXY FORMATION from gravitational collapse.

Cosmological significance

The fraction of baryons in the universe, calculated from the abundance of primordial light elements in the universe and predictions from the standard Big Bang model, is $\Omega_{\rm b}/\Omega_{\rm m} \sim 0.014\,h^{-2}$. However, various studies have claimed that on scales of about $15h^{-1}$ Mpc within the core of the Shapley concentration, the observed baryon fraction from the visible galaxies and the x-ray emitting hot gas is about $\Omega_{\rm b}/\Omega_{\rm m} \geq 0.04\,h^{-1.5}+0.02$, where the first term comes from the gas and the second from the galaxies.

If this is indeed borne out by future research, it would suggest that the baryon fraction observed over the scales of dozens of clusters might exceed that of an $\Omega_{\rm m} = 1$ universe by a factor of about 3. Detailed hydrodynamic simulations show that baryons do not segregate into rich clusters and superclusters to such overdensities within the age of the universe. The above results would therefore imply that either the mean density of the universe is $\Omega_{\rm m} \lesssim 0.3$, or that the baryon density is much larger than predicted by NUCLEOSYNTHESIS.

It is not clear on what scales superclusters are bound, but there is evidence of merging clusters in the cores of the richest concentrations of clusters. The Shapley concentration provides the best such example (figure 4), with tenuous evidence of x-ray emitting gas being detected outside the clusters at its core. It is the best laboratory we know of in which to study the formation of nonlinear structures in a dense environment. It is also the place to look for answers to questions like: what are the largest coherent bound structures? On what scales can they have dynamical influences on each other within the lifetime of the universe? On what scales do coherent peculiar velocities exist? What is the typical morphology of these structures? From the answers to such questions it is hoped that important clues to the history of galaxy and cluster formation will emerge.

Shapley, Harlow (1885–1972)

Born in Nashville, MO, he studied with FREDERICK SEARES and at Princeton with HENRY NORRIS RUSSELL, where he took over the analysis of Russell's observations of the light curves of 90 eclipsing binary stars (ten times the number known up to then). In this work he established that Cepheid variable stars, whose spectral lines mimic the spectroscopic binary stars, are in reality pulsating stars. He joined the staff of the Mount Wilson Observatory in California, moving to the study of globular star clusters. He discovered Cepheid variable stars in some and calibrating HENRIETTA LEAVITT'S period–luminosity relation, determining their distances. The asymmetric distribution of globular clusters on the sky meant that the Sun is off the center of the distribution, some 50 000 light years away in the direction of the constellation of Sagittarius. Shapley identified this with the center of our Galaxy. Although Shapley had underestimated interstellar absorption and thus overestimated the size of the Galaxy, this established the size of our stellar system. Shapley took part in the great debate with HEBER CURTIS and successfully demonstrated that our Galaxy was a star system comparable to other galaxies. Shapley became director of the Harvard College Observatory, establishing modern outstations at the Oak Ridge (later, Agassiz) Station west of Cambridge, MA, and by moving the Arequipa Southern Station in Peru to become the Boyden Station in South Africa, each equipped with a 60 in telescope. He used the Cepheid variable stars to investigate the Magellanic clouds, to probe the spatial distribution of external galaxies. He discovered the dwarf galaxies in Sculptor and Fornax.

Shen Kua (1031–95)

Born in Ch'ien-t'ang, Chekiang province (now Zhejiang), China, turned to science after a less than completely successful career as a general. He described his work on mathematics, astronomy, cartography, optics and medicine. He developed ideas on the motion of the planets which included techniques to predict retrograde motion, and used the techniques to improve predictions of the Moon. This led him to propose a new calendar, whose implementation required further observations of the sky, stimulating the development of astronomy in China. He made the first reference to a magnetic compass in his work *Meng ch'i pi t'an* (*Dream Pool Essays*). He also devised a celestial sphere, a bronze sundial and an improved clepsydra (water clock).

Shepherd Moon

A minor satellite whose gravitational influence on the particles of a narrow planetary ring constrains the ring's radial extent. The ring systems of the giant planets are all shaped by gravitational perturbations of the particles that make up the rings. A lone shepherd moon can give a broad ring a sharply delineated outer edge, while pairs of shepherd moons can 'squeeze' the particles of narrow rings into well-defined orbits.

Shepherd pairs were originally hypothesized in the late 1970s by Scott Tremaine and Peter Goldreich to account for the narrow rings of Uranus. In their model, one satellite orbits just outside a ring, and one just inside it. The outer shepherd moves more slowly than the ring particles. When a particle on the outside of the ring passes it, the ring drags it back, causing it to lose energy and fall into a slightly lower orbit. The inner shepherd, in contrast, moves faster than the ring particles, so when it overtakes a particle on the inside of the ring its gravitational attraction gives an energy boost to the particle, lifting it into a slightly higher orbit. The net effect is to counteract the natural tendency of the ring particles to spread out, so maintaining the narrow ring.

The theory received support with the discovery of such pairs of shepherd moons, first in the Saturnian system in 1981, and then in the Uranian system in 1986. The minor satellites Prometheus and Pandora orbit either side of Saturn's F ring. The clumpy, braided appearance of the F ring has been ascribed to the slightly different eccentricities of the two shepherds. Another minor satellite, Atlas, orbits right at the outer edge of the bright A ring, and appears to act as a shepherd, preventing the ring's particles from spreading outwards. Another pair of shepherds, Ophelia and Cordelia, were found to be orbiting either side of the ε ring around Uranus.

What is not clear is how other narrow rings can exist without the channeling effect of shepherds. It could well be that they are in fact shepherded by as yet undiscovered small satellites. On the other hand, some other mechanism could be playing a part in constraining the particles in them.

Shklovskii, Iosif Samuilovich (1916–85)

Soviet astrophysicist, educated and worked, particularly in radioastronomy, at Moscow State University and the Shternberg Astronomical Institute. He investigated the solar corona, showing that its temperature is of the order of a million degrees kelvin, and made theoretical and radio studies of supernovae and supernova remnants. In 1953 he proposed that the continuum radiation from the Crab nebula is synchrotron radiation, because of its broad spectral distribution, and predicted that the radio emission would be polarized by the magnetic fields causing the synchrotron radiation. This was demonstrated by Dombrovsky in 1954. From a very general theoretical model of how a supernova remnant expands into the interstellar medium he predicted the 1% per annum decrease of emission from the Cassiopeia A radio source, confirmed by Högbom and Shakeshaft in 1961. Shklovskii's book on *Intelligent Life in the Universe* was translated and expanded by CARL SAGAN.

Shoemaker, Eugene ['Gene'] Merle (1928–97) and Shoemaker, Carolyn [née Spellman]

Astrogeologist Gene Shoemaker was born in Los Angeles, California and became chief scientist at the USGS Center of Astrogeology (Flagstaff) and professor of geology at CalTech. He worked with his wife Carolyn on cratering, both on the Moon and the Earth, by volcanoes and by meteor and cometary impact. He discovered, with Edward Chao, coesite, a type of silica produced in a violent impact and a signature that a terrestrial crater is meteoritic. With Eleanor Helin, Carolyn and he searched for potential Earth-impacting asteroids. As a result of this search (through which they found 13% of all known asteroids), they also discovered 32 comets which now bear the Shoemaker name, including Comet Shoemaker-Levy-9 which impacted on Jupiter in 1996. Gene died in a car crash in Australia while visiting meteor craters.

Shoemaker–Levy 9–Jupiter Collision

The collision of comet Shoemaker–Levy 9 (SL9) with JUPITER, in July 1994, was an exceptional event for astronomers who were able to watch in real time the response of a planetary atmosphere to a large meteoritic impact. A wide variety of phenomena were observed such as temperature increase in the stratosphere, formation of aerosols and new gaseous species, and changes in the magnetosphere. Some of them remained visible in the following months and years. The observations were performed at all wavelengths, using all possible means from Earth and from space. Their interpretation has given an estimate of the size of the various impactors, their penetration level in the Jovian atmosphere, the energy released in the explosions, and the mass of the newly formed molecules. There is still uncertainty, however, about the chemical composition of comet SL9 itself.

The comet's history

Comet Shoemaker–Levy 9 was discovered in March 1993 by EUGENE AND CAROLYN SHOEMAKER and by David Levy, as a trail of about 20 individual fragments (figure 1). The study of its trajectory showed that it was a Jupiter-family comet (see COMETS) which was disrupted by tidal forces in July 1992 at its previous perijove passage, and that it would collide with the planet at its next perijove passage, in July 1994 (figure 2).

As a result of the discovery of comet SL9, a huge international effort took place using a wide variety of ground-based telescopes and instruments, working at all wavelengths from the ultraviolet to the radio range. Observations were also planned from spacecraft, in particular the HUBBLE SPACE TELESCOPE (HST) and GALILEO, but also the INTERNATIONAL ULTRAVIOLET EXPLORER (IUE) and the x-ray satellite ROSAT. Questions to be addressed were the amount of released energy, the temperature evolution, the size of the impactors, their physical nature and their chemical composition. In the meantime, the SL9 fragments, labeled from A to W, were repeatedly monitored from the the HST and ground-based telescopes between March 1993 and July 1994.

A collision of this type is very rare: according to the models of orbital dynamics, such an event might be expected once every few hundred years. A similar event might indeed have taken place about three centuries ago: as reported by the archives of Paris Observatory, Jean-Dominique Cassini reported in 1690 an unusual feature on the disk of Jupiter and his drawings show a remarkable similarity with the craters observed after the SL9 collision in 1994.

The fragments of comet SL9 entered the Jovian atmosphere between 16 July and 22 July 1994, at a latitude of -44°, only a few minutes within the dates predicted by astrometry. The impacts took place just behind the limb, and came into direct viewing from Earth about 10 minutes later, due to Jupiter's rotation. The Galileo spacecraft, then at a distance of 1.6 AU from Jupiter, benefited from a direct viewing of the impacts. During the week of impacts, all fragments collided on the $l = -44^\circ$ parallel, at different longitudes, as an effect of the planet's rotation. All explosions were extensively studied from almost all observatories; a huge temperature increase was measured in the stratosphere of Jupiter, dust was formed and new molecules were detected; changes were reported in the magnetosphere (see JUPITER: MAGNETOSPHERE).

The impacts

Three types of data have been recorded during the impacts: (a) the lightcurves, at different visible and infrared wavelengths, have given the temperature evolution and the energy budget; (b) images taken from the ground, from the HST and from Galileo, have shown the meteor entry, the ejecta trajectories and crater evolution; (c) spectra, recorded in the ultraviolet, visible, infrared and radio range have shown evidence for new species. For all observed impacts, from the recorded lightcurves, events can be interpreted as a sequence of three main phases (figure 3): the 'entry' phase, the 'explosion' phase and the 'splash' phase. The entry phase, which took place behind the limb as seen from Earth, was mostly observed by Galileo and we have little information about it; it was sometime detected as a first weak emission in the ground-based lightcurves. The explosion phase, about 1 min later, was observed as a strong emission, especially in the visible range, corresponding to the explosion of the impactor within the atmosphere and the ascension of the fireball; here again, most of our knowledge about this phase comes from Galileo. The splash phase, which starts about 6 min after the explosion and lasts for about 15 min, corresponds to the heating of the Jovian stratosphere by the ejecta as they fall back on the planet; this phase was extensively studied from Earth. The intermediate period between these two last phases was mostly observed by the HST which was able to measure the maximum altitude reached by the EJECTA (over 3000 km).

The entry phase

The lightcurve of the entry phase or 'meteor phase' has been mostly observed by the imaging system (SSI) and the photopolarimeter (PPR) of the Galileo spacecraft. Several ground-based observatories also recorded a weak, early event, about 1 min before the explosion itself; it probably corresponds to a meteor storm accompanying the main fragment.

Several attempts have been made to detect light echoes on Galilean satellites, but they were all unsuccessful; the corresponding upper limits for the radiated energy are compatible with the estimates derived from the Galileo lightcurves.

The explosion phase

From a modeling of the lightcurves by Crawford, McLow and Zahnle, and with the use of the plume altitudes observed with the HST, estimates of the fragment diameters have been obtained. They range between 150 m

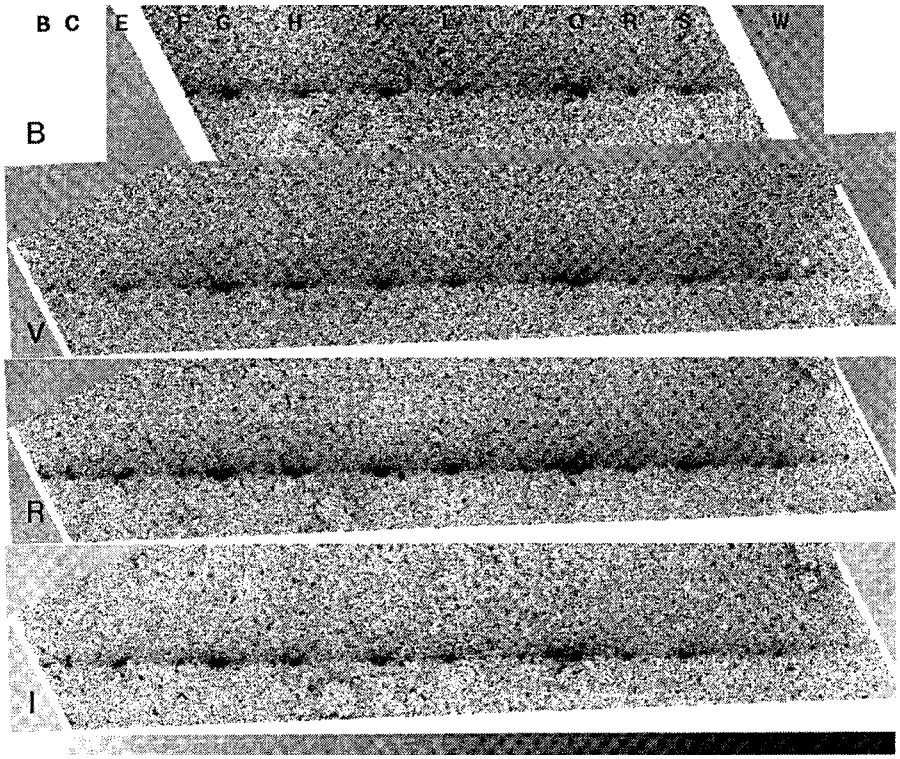

Figure 1. The fragments of comet Shoemaker–Levy 9 as observed from the 3.5 m New Technology Telescope (NTT) at ESO, La Silla, on 1 and 2 July 1994. About 12 of the 20 identified fragments, labeled from A to W, are visible in theses pictures (from top to bottom: filters B, V, R and I). The figure is taken from Stüwe *et al* in West and Bohnhardt (1995, pp 17–22).

and 600 m, which corresponds to H_2O masses of 2×10^{12} and 10^{14} g respectively. These values also agree with the estimate deduced by Asphaug and Benz from the trajectories of the cometary fragments after disruption. Calculations show that the altitude reached by the ejecta is about the same (about 3000 km) for all fragments whatever their size is, as the smaller fragments explode at a higher level than the more massive ones. The total energy released is about 3×10^{27} erg for the biggest impactors (K and G impacts), and about 10 times less for the smaller ones. However, even in the case of the big impacts, the energy is not sufficient to lead to detectable seismic waves, for which only an upper limit was obtained by Galdemar and Mosser.

The temperature of the fireball resulting from the explosion has been estimated by Martin and Orton from the visible and near-IR lightcurves measured by the Galileo SSI, NIMS and PPR experiments. From over 10 000 K at the beginning, it decreased to about 2000 K after about 15 s. According to the NIMS data, the size of the fireball increased adiabatically from 15 km, 10 s after the explosion, to 100 km after 40 s. There is still some uncertainty about the penetration level of the fragments, as some observations (including infrared emission lines of NH_3) suggest that the explosion of the biggest fragments took place below the NH_3 cloud, at a pressure higher than 0.5 bar, while the interpretation of the Galileo NIMS observations favors a higher penetration level, at about 0.2 bar. In any case, the explosions are likely to have taken place in the upper troposphere or near the tropopause, in the pressure range 0.1–1 bar.

The splash phase

Information upon the temperature evolution in this third phase comes from the lightcurves, but also from the spectra of the emission bands of CH_4, especially in the strong ν_3 band around 3.3 μm. Methane, a spectroscopically very active gas, is one of the main minor constituents of the Jovian atmosphere (see JUPITER: ATMOSPHERE) and its mixing ratio, with respect to the main constituent H_2, is well known (about 2×10^{-3}). From its emission spectrum, one can derive the temperature of the emitting region. Measurements obtained by this method indicate a decrease from about 1000 K at $T = 10$ min down to about 600 K at $T = 25$ min.

Apart from the information about the temperature, spectra obtained during the splash phase have led to the discovery of new species, both gaseous and solid. The presence of dust was visible in the early part of the splash phase, with the formation of dark craters at the center of the impacts, surrounded by crescent-shaped areas due to infalling ejectas (figure 4). Infrared spectra have shown the presence of silicates, which suggests, for the impactor, an O/C ratio larger than 1, and a cometary origin. The dust

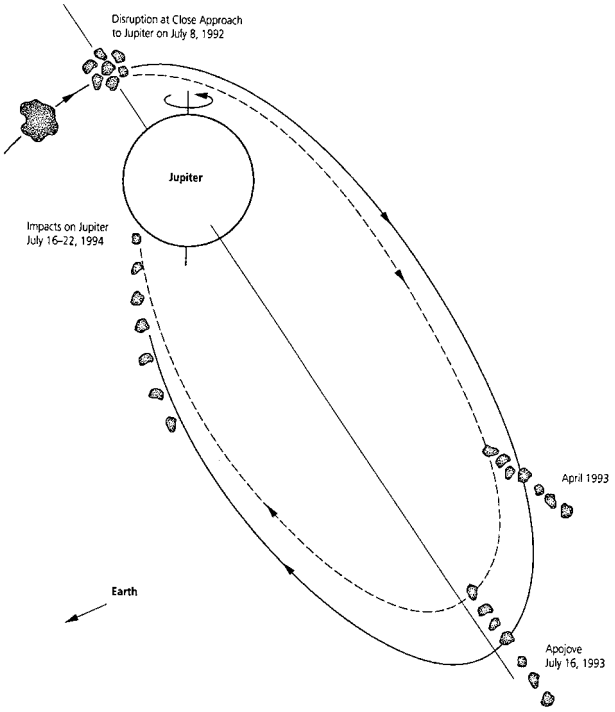

Figure 2. The orbit of comet SL9 between July 1992 (time of tidal break-up) and July 1994 (time of collision with Jupiter). This schematic diagram is not drawn to scale. (Prepared by Z Sekanina, P Chodas and D Yeomans.)

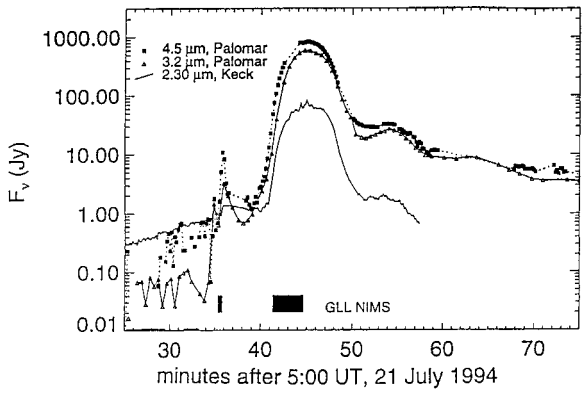

Figure 3. Lightcurves of impact R, observed with the Keck (10 m) and Palomar (6 m) telescopes at three different infrared wavelengths. The black bars indicate the time intervals at which NIMS–Galileo observations were recorded. The time of explosion is 05:34:57 (Chodas and Yeomans 1996). The first weak maximum corresponds to the entry phase ($t = -1$ min). The second maximum corresponds to the explosion phase ($t = 0$–2 min) and the third maximum, brighter and extended in time, corresponds to the splash phase ($t = 6$–25 min). The figure is taken from Nicholson (1996).

probably also contains a carbonaceous component, but no firm identification could be derived from spectroscopy. The total volume of dust injected in the stratosphere has been estimated by West to make up a sphere of about 1 km diameter, with particles of 0.25 μm diameter. From their infrared signature, the total mass of the silicates has been estimated to 8×10^{13} g, or 10–20% of the total volume of the impactor.

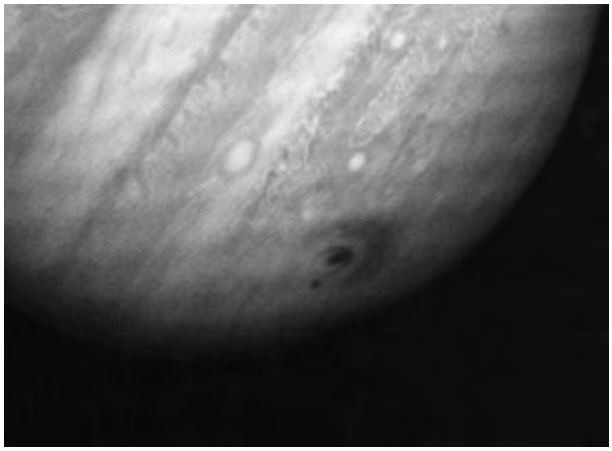

Figure 4. This image, taken with the wide-field camera of the Hubble Space Telescope, shows the impact craters for fragments D and G. The larger crater was created by impact G on 18 July 1994. The central hole is distinctly surrounded by two concentric rings. The smaller crater on the left of the G impact site is due to impact D which took place a day earlier. This image was taken 1 h 45 min after impact G (Hammel, NASA, ESA).

Many new gaseous species have been detected in the stratosphere during the splash phase: CO, H_2O, S_2, CS_2, CS, OCS, HCN, C_2H_4, NH_3 (previously present mostly in the Jovian troposphere), and possibly PH_3 and H_2S. These discoveries and their implications have been reviewed by Lellouch. The most abundant of the newly formed species was CO, detected both in the infrared and in the radio range. A remarkable result was the high excitation temperature deduced from CO infrared observations, which increased from 2000 to 5000 K during the first 10 min of the splash phase. In contrast with other molecules, CO is not dissociated at these temperatures. The temperature increase has been explained by Zahnle on the basis of a ballistic model, in which the CO molecules having the highest excitation temperature are the ones which, being lifted at highest altitudes, fall down later. H_2O was detected in the beginning of the splash phase; it was observed both by the near-infrared spectrometer of Galileo (NIMS) and from the Kuiper Airborne Observatory; its excitation temperature was about 1000 K. S_2, CS_2, CS and possibly H_2S (although this latter detection is tentative) were found from ultraviolet spectroscopy with the HST. In addition to CO, ground-based millimeter heterodyne spectroscopy provided the detection of HCN, CS and OCS, while C_2H_4 and HCN, together with NH_3 emission lines, were found in the infrared region, at 10–13 μm. The infrared and millimeter spectroscopic observations have also provided key information about the evolution of the stratospheric thermal profile.

			1×10^{14} [C]	2×10^{14} [C]	3×10^{13} [C]
PH_3	IR	?	3×10^{11} [P]	1×10^{12} [P]	
Silicates	**IR**	6×10^{12}	8×10^{13} [Si]	1×10^{14} [Si]	
				4×10^{13} [Mg]	1×10^{14} [Mg]

† In bold are the observations from which the abundances are taken.
‡ Some of these values are preliminary and subject to revision.

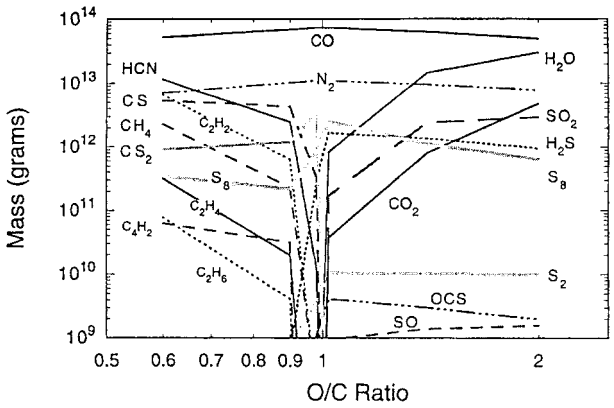

Figure 5. Total production of a mass of gas, 50% Jovian and 50% cometary, produced by a comet of 10^{14} g, as a function of the cometary O/C ratio. This model assumes gaseous phase chemistry. The production corresponds to temperatures ranging from 1500 to 5000 K. Comparison with table 1 shows that the global composition of the newly formed species cannot be explained by a single value of the O/C ratio. The figure is taken from Zahnle (1996).

The relative abundances of the newly formed species can provide information about the chemical nature of the impactors. Assuming that the emitting region is formed with material containing 50% of Jovian material and 50% of cometary matter, Zahnle has calculated the expected relative abundances of the expected new molecules, as a function of the O/C ratio (figure 5). If oxygen dominates, the expected new species are CO, N_2 and H_2O, then SO_2, SO and CO_2. In contrast, if carbon dominates, then CO, N_2, CS, HCN, C_2H_2, CH_4 and CS_2 are expected. The puzzling result is that the newly formed species belong to the two lists, which makes the interpretation difficult. This might imply that the chemical composition was different for the various impacts, but the origin of such differentiation would remain to be explained. Inversely, if a cometary O/C ratio is assumed, then the relative abundances observed for the new species imply that the emitting region must have been mainly formed of Jovian gas.

Another surprising result was the detection, in the visible range, of a large number of atomic and ionized lines at the beginning of the splash phase. In particular, lithium was observed for the first time in an outer solar system body. These emissions have to be of cometary origin; however, as discussed below, it is difficult to derive the cometary abundances of these species, because their excitation mechanism is not fully understood at present.

The long-term evolution of impact phenomena

An extensive monitoring of the Jovian disk, both by imaging and spectroscopy, took place during the months following the impacts, and some of the observations have been periodically repeated during the three following years.

Evolution of the thermal profile

The thermal evolution of the Jovian stratosphere has been studied using the spectral profiles of the various emission lines observed during and after the impacts: CH_4 at 8 μm, C_2H_2 at 13 μm, CO at 4.7 μm, and CO, CS and HCN in the millimeter range. The stratosphere cooled rapidly (figure 6), and had returned to its nominal temperature within about a month; this rapid cooling has been explained by Bezard, taking into account the presence of the silicate particles injected into the stratosphere at the time of the explosion, which efficiently contribute to its radiative cooling.

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

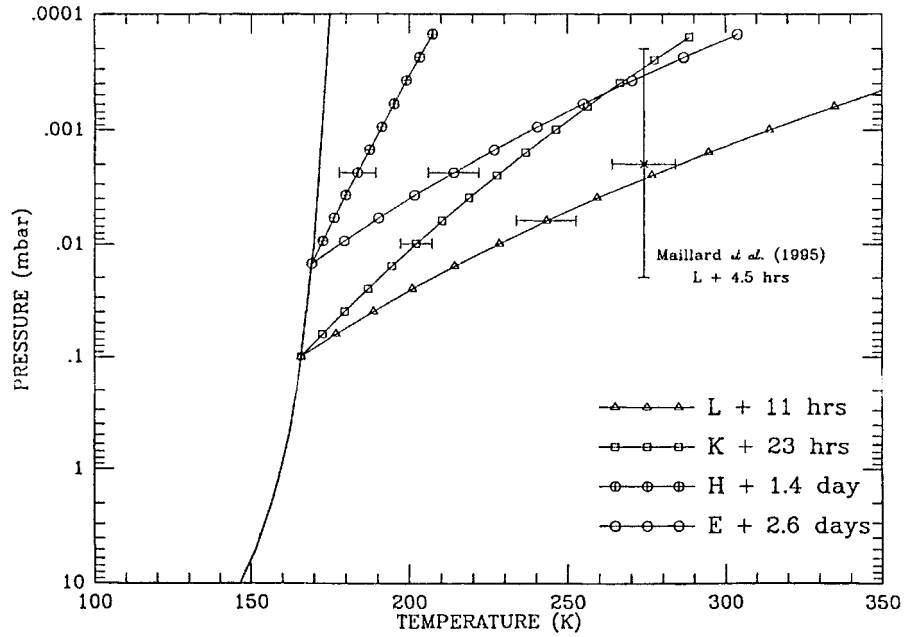

Figure 6. Evolution of the Jovian stratospheric temperature after impacts L, K, H and E. Calculations of radiative cooling show a faster cooling than anticipated by the Jovian gases only, which can be explained by the effect of newly formed silicates. The figure is taken from Bézard *et al* (1997).

Evolution of the newly formed molecules

The newly formed species had very variable lifetimes. H_2O disappeared after a few hours, while S_2, OCS and NH_3 lasted for a few weeks. CS_2 and CO were detectable for several months; CS and HCN lasted several years. A good general agreement was found between the observed evolution of these species and the predictions provided by the photochemical evolutionary models developed by Moses.

Evolution of the dust

The clouds formed at the time of impacts were extensively monitored in the weeks and months following the impacts. The horizontal dust distribution was observed with UV HST images and ground-based images within the CH_4 bands, probing the high stratosphere. The clouds first spread in longitude during the first few days, as an effect of the fast rotation of Jupiter. Then they elongated to form a continuous dark band along the -44° parallel. During the year following the collision, they spread in latitude, between -20° and -80°. The density of aerosols was reduced by a factor 4 to 10 after 10 months; the aerosol layer was still weakly detectable after one year.

Dust particles were originally located at high stratospheric levels, stable against convection, and they were sufficiently light to have a residence time of about a year, as estimated by West. Their vertical motion was monitored through the evolution of the stratospheric profile, as they are mostly responsible for its cooling. After a year, the areosol layer had reached the tropopause level at 0.1 bar.

The morphology of the ejecta showed two concentric rings which expanded at constant velocities of about 450 m s^{-1} for the outer ring and 210 m s^{-1} for the inner ring; it was suggested by Ingersoll that they possibly originated from waves. The radial speed of the outer ring, however, is too slow for an acoustic wave and too fast for a gravity wave, so that the origin of the rings is still an open question.

Magnetospheric effects

The radio emission

The radio emission of Jupiter has three types of components: the thermal millimeter radiation, the synchrotron emission of the electrons along the magnetic field lines, in the centimeter–decimeter range, and the outbursts from localized radio sources, in the decametric range.

The Jovian magnetosphere has also been perturbed by the collision. If little change was observed at decimetric or decametric wavelengths, the synchrotron radiation, observed in the centimeter range, showed a significant enhancement (by 10 to 40%) during the week of impacts, as well as some modification of its properties. Most of the emission was confined to one hemisphere, between 100 and 240° longitude. The observations apparently imply the existence of a population of newly excited electrons which are confined in a particular region of the magnetic field. The hemisphere of maximum radio emission correlates with the side where the magnetic field lines crossing the radiation belts intercept the Jovian disk in the region of latitude -44°, i.e. where the impacts took place. Several mechanisms have been proposed

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

for the origin of the new population of electrons: radial diffusion enhancement, shock acceleration and pitch angle scattering; as discussed by Bolton, more than one mechanism is probably required to account for the observed data.

Auroral phenomena

Changes have been also recorded in the AURORA of the planet. The first sign of auroral activity may have been an Mg^+ flash fortuitously recorded from the HST at the G-condensation, on 14 July 1994, four days prior to the entry, presumably corresponding to the G-entry in the Jovian magnetosphere. Other UV signatures were recorded from the HST in the H and H_2 lines a few hours before the impacts; they were probably emitted in auroral flares when the fragments crossed high L-shell magnetic lines. A strong infrared H_3^+ emission was recorded a few minutes before the C impact, implying a strong heating of the upper stratosphere.

A remarkable result was the detection of emissions, on several occasions, at the location of the northern counterparts of the impacts (the footprints of connecting magnetic field lines): such an x-ray emission was observed by the ROSAT satellite at the time of the K and P2 impacts; UV emissions of norther counterparts were recorded by the HST just after the splash phase (t = 30–60 min), and infrared H_3^+ emissions of northern counterparts were reported a few days after the impacts. As reviewed by Ip, all these results, together with the observed enhancement of the synchrotron radiation, suggest that field-aligned current systems established a connection between the impact sites and their magnetic conjugate points.

The auroral activity of Jupiter was monitored in the UV with the IUE satellite during the impacts, and in the IR from ground-based H_3^+ observations during the week following the impacts. An enhancement of the northern auroral emission was recorded a few days after the last impacts: its ratio to the southern emission increased to a value of 7–8 on 25 July, and then returned to its normal value of 1–3. The decrease of the southern aurora may have been associated with chemical effects induced by newly formed material reaching high southern latitudes.

What have we learnt about comet SL9?

History of SL9

On the basis of more than 3000 astrometric measurements, Chodas and Yeomans have been able to predict with high accuracy the impact times of all fragments. The set of predicted impact times was systematically early by about 7 min, probably due to systematic errors in the reference star catalogs used for the data reduction. The timing of the impacts as measured by Galileo was found to be accurate within 10 s of the predictions, corrected from the systematic effect, while the impact timing derived from ground-based observations was accurate to within a few minutes. Using the observed impact times, new orbit solutions were generated, leading to the best orbital fits ever obtained for a comet.

On the basis of its retrieved orbit, the pre-break-up history of comet SL9 has been inferred by Chodas and Yeomans, using a Monte Carlo analysis. The progenitor of comet SL9 was most likely captured by Jupiter around 1929 $\pm$ 9 years. Before capture, the comet was in a low-eccentricity, low-inclination heliocentric orbit, probably inside Jupiter's orbit, consistent with a group of Jupiter-family comets called the quasi-Hildas.

Evolution and activity of SL9

Studying the possible break-up scenarios of comet SL9 can provide important constraints upon its internal strength. Two extreme models have been proposed, with on the one hand a coherent body subject to sequential crack formation, and on the other side a rubble pile/swarm model. Neither of them is fully satisfactory, which led Rickman to propose a new scenario involving processes from both models. He estimated the tensile strength of the comet to be about 100 Pa, a very low value consistent with a fluffy aggregate of sub-micron particles.

Asphaug and Benz have modelled the elongation of the swarm, on the basis of tidal forces and self-gravity, and they have calculated the expected chain length as a function of the comet density and the size progenitor. Comparison with the actual chain length favors a 1.5 km progenitor with a density of 0.5 g cm^{-3}. This estimate is consistent with the mean size of the impactors derived from the dynamical simulations.

The activity of the comet prior to the impact has been studied from the HST and ground-based images. The break-up of the comet apparently triggered the activity of the fragments which were continuously surrounded by a dust coma from July 1992 to July 1994; estimates of dust production rate are rather low (between 1 kg s^{-1} and 5 kg s^{-1} for the largest components). All attempts to detect gaseous activity, in the visible, near-UV and radio range, were unsuccessful. Upper limits of production rates were in the range of 10^{27} s^{-1} for OH, and 3×10^{23} for CN. Taking into account the small size and the low dust production rate of SL9, the absence of a gaseous signature in its spectrum is not surprising.

Chemical composition of SL9

A spectacular result was the ground-based detection of the atomic lines in the visible range, in the splash phase of impacts L, Q1 and Q2. The observed species were Fe, K, Ca, H, Na, Mn, Mg, Cr and, for the first time, Li. Other atomic and ionic transitions were also detected in the UV from the HST: H, He, S, Si, Mg^+, Fe^+, Si^+, Al^+ .... All these elements, absent from the Jovian outer atmosphere, are indubitably coming from the impactor; their signatures are also found in the spectra of sungrazing comets. These emissions are usually excited by fluorescence. However, as discussed by Crovisier, this mechanism does not seem to be responsible for the SL9 emissions, or at least it cannot be the only one: the observed lines are heavily saturated, and their intensities and widths are too large to be explained by fluorescence. Other possible mechanisms

could include thermal excitation by collisions, electronic recombinations, or prompt emissions following chemical reactions; all these time-dependent excitation phenomena are unfortunately very difficult to model. No firm conclusion can thus be derived at present about the abundances of the observed atom and ion species.

The chemical composition of the comet is also difficult to retrieve from the newly formed molecules. Indeed, all cometary elements must have been vaporized at the time of the explosion; the new molecules observed are not coming directly from the comet, but are recombination products, most likely formed in the early part of the splash phase. In addition, the newly formed species can be partially of planetary origin, so that even the atomic abundances derived from their mass may not necessarily provide reliable determination of the comet elemental masses.

Some information, however, can be retrieved from the relative abundances of the newly formed species; this study has been performed, in particular, by Lellouch and Crovisier (table 1). The oxygen- and sulfur-bearing species are known to be absent from the Jovian stratosphere; their abundance can thus be used to infer the cometary mass of oxygen and sulfur. The derived values are 5×10^{12} g for S and $(1–3) \times 10^{14}$ g for O; the derived S/O ratio is compatible with both cometary and asteroidal abundances, and does not allow us to discriminate between the two origins. The cometary abundance of carbon cannot be retrieved from newly formed carbon-bearing species, as carbon might come from Jovian CH_4. The case of nitrogen is more dubious: some newly formed NH_3 was probably of cometary origin, but some may have come from the NH_3 cloud if this cloud was hit by the meteor. The derived abundance of stratospheric nitrogen was 10^{13} g. Assuming an impactor origin for N, the inferred N/O ratio would clearly favor a cometary origin.

Another important parameter is the composition of aerosols. The signature of silicates was identified at 10 μm, leading to an estimate of 8×10^{13} g for the Si abundance. The inferred S/O ratio is in good agreement with a cometary composition.

Was SL9 a comet or an asteroid? Although no definite conclusion can be drawn on the basis of its chemical composition, several arguments strongly favor the cometary origin: the small size, the activity level, weak but real, the low density and the low tensile force, and the silicate signature. SL9 was most probably a small, very common Jupiter-family comet which would never have caught astronomers' attention without its premature death in a crash with Jupiter.

Conclusions

Several years after the collision, there is still work to be done on the modeling and interpretation of the huge database collected at the time of impacts and in the following weeks and months.

The coordinated observation of the entire impact has allowed a repeated intercomparison of all observations, and their interpretation in the light of theoretical impact models and fireball evolutionary models. There is a good overall understanding of the general phenomenon, which has allowed a determination, at least to first order, of the main physical parameters involved in the collisions: energetic budget, size of the fragments, penetration levels. The abundance of newly formed species has been analysed in the light of shock chemistry models, and their temporal evolution is in good agreement with the predictions of photochemical evolutionary models.

From the global set of astrometrical measurements, the history of the comet has been determined with high precision. However, the physical and chemical nature of the comet itself is still poorly known. In summary, one could say that the collision of comet Shoemaker–Levy 9 with Jupiter has not allowed us to fully understand the nature of the comet; in contrast, it has provided a huge amount of information about the physics of large meteoritic impacts, as well as on the behavior of a planetary atmosphere after such impact.

Short-period Comet

A comet whose period is less than 200 years, also known as a *periodic comet*. Comets with longer periods are termed *long-period comets*; these are also 'periodic', but a comet can be incontrovertibly classified as periodic only when it has been observed on at least two returns. The choice of 200 years as a cut-off is a historical convenience, corresponding roughly to the length of time for which it has been possible to calculate orbits with sufficient accuracy to predict a return; also, no comet with a calculated period of more than 200 years has yet been observed to return since its discovery. In the system of cometary designations introduced in 1995, a short-period comet is assigned the prefix 'P/' and a number indicating the order in which the periodicity of its orbit was established, in a sequence beginning with 1P/Halley. As of April 2000 there were 143 known short-period comets. In addition there are over 40 comets with calculated periods of less than 200 years that have been observed at only one return, plus some two dozen short-period comets that have failed to show up when expected or have been observed to disintegrate.

Most short-period comets have orbital inclinations of less than 30° (15° is typical) and move in direct orbits. The shortest period, 3.3 years, is possessed by 2P/Encke; the longest, 155 years, by 35P/Herschel–Rigollet. Many short-period comets have been perturbed into their present orbits by the gravitational influence of Jupiter and have aphelia near 5.2 AU, Jupiter's distance from the Sun, and orbital periods of 6 to 12 years—in fact, three-quarters of all short-period comets have periods that fall within this range. These so-called *Jupiter-family comets* are believed to have originated in the Kuiper Belt. Those with periods of 20 to 200 years, known as *random* or *Halley-type comets*, are, like the long-period comets, thought to come from the Oort Cloud.

Sidereal Period

A period of time measured relative to the 'fixed' stars. In normal usage the term refers to the time taken by a planet to complete one orbit of the Sun, returning to its original position relative to the position of the stars, or the time taken for a satellite to complete one orbit of its parent planet, again measured relative to the background stars. In the case of the Earth, this period of time is referred to as the sidereal year and is equal to 365.2564 mean solar days.

See also: synodic period.

Sidereal Time

A time system based on the rotation of the Earth measured relative to the background stars, which for this purpose are regarded as fixed in position. Relative to the stars, the Earth rotates on its axis in a period of 23 h 56 min 04.1 s of mean time (i.e. ordinary civil time), and this period is called the sidereal day, which is, in turn, divided into sidereal hours.

For an observer located at a particular longitude on the Earth, the sidereal day is equivalent to the apparent rotation period of the celestial sphere. This period may be determined by measuring the interval between two successive upper transits of a given star across his meridian. The value of the sidereal time at any instant is defined to be the hour angle, i.e. the angle measured clockwise from the meridian, of the vernal equinox (a fixed point on the celestial sphere). Thus, when the vernal equinox is on the meridian, its hour angle is zero, and the sidereal time is zero hours. By the time that the rotation of the celestial sphere has increased this angle to 90°, 6 h have elapsed, and the sidereal time is 6 h, and so on. After 24 h, the vernal equinox returns to the meridian.

The hour angle measured by this observer relative to his meridian is the local hour angle, and the sidereal time so obtained, the local sidereal time (LST). Greenwich sidereal time (GST) is the hour angle of the vernal equinox measured from the Greenwich meridian. The difference between LST and GST corresponds to the longitude of the observer expressed in time units (where 1 h is equivalent to 15°, since the Earth rotates through 15° per hour). If the observer is east of Greenwich, LST is greater than GST, if he is west of Greenwich his LST is less than GST.

See also: equinox, hour angle.

Siderostat/heliostat/coelostat

A plane mirror that is driven about an axis so as to reflect light from a particular celestial object along a fixed direction. In practice, a coelostat usually comprises two plane mirrors. One mirror is driven around an axis parallel to that of the Earth at half the Earth's rotation rate in order to counteract the apparent rotation of the celestial sphere and ensure that rays from a particular object are reflected along a constant direction. The other mirror is orientated so as to reflect the beam of light from the first mirror into a fixed telescope. A siderostat uses a mirror driven at the same angular rate as the rotation of the Earth but suffers from the drawback that although a star located at the center of the field of view remains stationary, the rest of the field of view rotates about that central point.

Where the mirror, or mirrors, is (are) driven to follow the apparent motion of the Sun, the device is called a heliostat. Systems of this kind are used in a number of specialist solar telescopes. For example, the McMath solar telescope at Kitt Peak, Arizona, uses a 2 m diameter heliostat, mounted at the top of a 30 m tower, to reflect light down a cooled inclined tunnel, about 150 m long, to a reflecting telescope system that produces a fixed image of the Sun, some 76 cm in diameter, in a laboratory.

Sigüenza y Gongora, Carlos de (1645–1700)

Spanish colonial astronomer, born in Mexico City, became professor of astrology at the university but seems strongly to have opposed astrology and, in 1681, wrote on comets to calm fears aroused by the one of 1680–1. Appointed by decree of Charles II of Spain as royal cosmographer, he mapped New Spain, Mexico and Pensacola Bay and determined the longitude of Mexico City. He published almanacs and observed the solar eclipse of 1691.

Sikhote Alin Meteorite

An iron meteorite that fell in the Sikhote Alin mountain range in southeast Siberia on 12 February 1947. It was preceded by a brilliant fireball. The incoming body fragmented at a height estimated at about 5 km, and the fragments produced nearly 400 small impact craters, the largest 27 m across. The total of 23 tonnes that was collected included a fragment with a mass of 1.7 tonnes. According to some estimates there may be as much as 75 tonnes of material uncollected.

Sirius

Sirius is the brightest star in the night sky and lies in the constellation CANIS MAJOR. In reality, Sirius is a BINARY SYSTEM consisting of a main sequence star (Sirius A) and a WHITE DWARF companion (Sirius B). Other common names for this star system include Canicula, Aschere and the Dog Star.

Canis Major, which translates to the greater dog, is one of the hunting dogs of Orion, with CANIS MINOR being the other. The Sirius binary star system represents the nose of the greater dog, and can be easily found by following the line made by the three stars comprising the belt of ORION.

Several centuries ago, Sirius was believed to be a single star. In 1862, nearly 20 years after a companion star to Sirius A was first suspected to exist, ALVAN CLARK discovered Sirius B while testing a new lens he had made for Dearborn Observatory. The location of this binary system in the sky is at right ascension $06^h\,45^m\,09^s$ and declination $-16^\circ\,42'\,57''$. The distance to these two stars is 8.6 light years, or just over 80 trillion kilometers. Sirius A and Sirius B constitute a VISUAL BINARY, which means that each of the two stars can be individually resolved through the use of a telescope.

Sirius A, which has a spectral type A1 V, is considerably larger than our own Sun. Sirius B, spectral type DA, is roughly four times the size of the Earth. Although the ratio of the sizes of these two stars is roughly similar to the same ratio for the Earth–Sun system, the mass ratios of the two pairs are quite different. It would not be unreasonable to approximate the Earth–Sun system as the Earth moving in a nearly circular path about a fixed Sun. Sirius A and Sirius B, however, must be considered as two stars that each orbit about their common center of mass. It should be noted that the Earth and Sun also orbit about their own common center of mass, but that lies very close to the center of the Sun while center of mass of the Sirius system is relatively well removed from either star.

The apparent magnitude for Sirius A is -1.5, which makes it appear to be the brightest star in the night sky; its absolute magnitude is 1.4. The apparent and absolute magnitudes for Sirius B are 8.3 and 11.2, respectively. Note that the difference between absolute and apparent magnitudes for each star is the same. This is a direct result of the fact that they are at the same distance.

The evolutionary state of the Sirius binary system today is quite different from what it must have been in the past. Sirius B, which is now a white dwarf, was most likely a RED GIANT. When the old Sirius B exploded, its core remained behind to become the Sirius B we are familiar with today. Estimates for the earlier Sirius binary system place the mass of Sirius B near four solar masses, the separation between the two stars at seven astronomical units, and the orbital period about the center of mass at seven years.

Sirius A recently provided the first proposed detection of a stellar wind from a spectral type A star. There is no currently known mechanism capable of initiating a stellar wind in A-type stars. However, if such a mechanism does exist, it is believed that radiation pressure would be capable of fueling such a wind. The nearby proximity of Sirius A, along with its white dwarf companion, provides a unique environment in which to search for such winds and their origin.

An intriguing puzzle has surrounded Sirius A for nearly two thousand years. Specifically, observations by PTOLEMY and others suggest that Sirius A was considerably redder during their time. Several theories suggesting mechanisms capable of producing the observed color differences within a time frame of 2000 years have been investigated. One of the more viable explanations is that Sirius A appeared redder due to interference caused by the Earth's atmosphere, given the position from which Ptolemy was most likely to have made his observations.

Because Sirius B has a mass very close to that of our Sun confined within a sphere whose radius is less than five times the radius of the Earth, the gravitational attraction at the surface of Sirius B is extremely high (more than two million times that felt on the surface of the Earth). It is so high, actually, that it causes a REDSHIFT in the light emitted from Sirius B.

Sirius B is also intriguing in that it is one of the most massive white dwarfs detected to date. Although it is very close as far as astronomical distances are concerned, observations are made quite difficult due to its association with Sirius A. Newer, more accurate measurements for the basic properties of Sirius B can help us to understand not only the Sirius binary system, but also our universe as a whole.

Sitterly, Charlotte Emma Moore (1898–1990)

Astrophysicist and atomic physicist, worked with HENRY NORRIS RUSSELL at Princeton on binary stars and their masses. She worked at Mount Wilson with Charles E St John and HAROLD BABCOCK analysing the atomic lines in the sunspot spectrum. At the National Bureau of Standards and the Naval Research Laboratory she analysed laboratory data on the solar spectrum and the atomic data by which spectral lines are characterized; towards the end of her long life she was still working extending the tables into the ultraviolet for use with data from space instruments.

Skylab

The NASA Skylab space station was launched from Cape Kennedy, Florida, on 14 May 1973 with the Saturn V rocket. It went into a 93 min low-Earth orbit with an altitude of 433 km and an inclination of 50°. The Apollo telescope mount (ATM) of the Skylab space station carried a suite of instruments of unprecedented spatial resolution that made solar observations leading to significant advances in solar physics. These instruments were originally developed in 1965 for a NASA mission known as the Advanced Orbiting Solar Observatory (AOSO), which was intended to provide high-spatial-resolution solar observations as a successor of the ORBITING SOLAR OBSERVATORY series of solar missions. Cancellation of the AOSO program in late 1965 led to a plan to fly the experiments on the ATM by 1969, near the maximum of solar activity. Changes and delays in the Skylab program resulted in the 1973 launch during the decline in the solar activity cycle.

The Skylab space station (figure 1) consisted of the 15 m long orbiting workshop (OWS), which provided storage space and crew quarters. That was joined to the multiple docking adapter, which housed the ATM control and display panel (figure 2) and provided a docking port for the Command and Service Module, which ferried the astronauts to and from Skylab. The ATM consisted of an outer rack structure attached by a gimbal system to an inner 3 m long canister that could rotate, pitch and yaw relative to the rack. The canister housed the solar instruments. The ATM optical bench for the instruments was a stiff cruciform structure dividing the canister length into four quadrants. The pointing capability of the ATM, critical for the success of the solar observations, was achieved by a pointing control system that sensed Sun center and sent error signals to the torque motors controlling the ATM canister gimbals. The yaw and pitch stability over minutes of time was about 0.5 arcsec, considerably exceeding the nominal 2.5 arcsec specification. Offset pointing was accomplished by the astronaut with a panel joystick.

ATM observations were conducted over three manned missions (SL-2, 3 and 4), each consisting of a crew of three astronauts who lived and worked on the station. Following Skylab launch problems that threatened the mission, the SL-2 crew carried out the first major repair work in space by erecting a parasol that replaced a lost thermal shield and by deploying the closed solar array on the OWS. The SL-2 mission lasted 28 days, from 25 May to 22 June 1973; SL-3 59 days, from 28 July to 25 September 1973; and SL-4 84 days, from 16 November 1973 to 8 February 1974. These missions permitted about 9 months of solar observations. After the SL-4 mission, Skylab was inoperative and re-entered the atmosphere 11 July 1979.

ATM instruments and operations

The ATM suite of solar instruments consisted of six primary and seven auxiliary instruments. The Skylab instrument numbers, names, sponsoring institutions and brief descriptions were as follows.

Figure 1. View of Skylab from the Sun. The OWS is at the top, covered with a parasol and sunshade. The one OWS solar array is at the upper left; the diagonal arrays supplied power to ATM. The ATM doors and experiment access ports are shown in the circular structure at the lower center. From Eddy (1979).

S052: White Light Coronagraph. The HIGH ALTITUDE OBSERVATORY *(HAO):* The instrument provided white-light images of the full CORONA in the altitude range of about 1.5 to 6 solar radii with a spatial resolution of 8 arcsec. Light from the solar disk was blocked by a series of three external disks and an additional adjustable internal disk behind the primary objective lens. The light passed through several lenses and mirrors and a polaroid wheel to the focus on a removable film camera. The polaroid wheel had one clear position and three polaroid positions with 60° differences in orientations. A movable mirror permitted the beam to be sent to a TV camera which provided a real-time image for crew observation and ground transmission. More than 35 000 exposures were obtained on 35 mm film from both manned and unmanned missions.

S054: X-ray Spectrographic Telescope. American Science and Engineering (AS&E): The instrument used a grazing-incidence Wolter system of concentric and confocal mirrors to form a full-disk solar x-ray image at the focus on a removable film camera. A prefilter and six-element filter wheel provided various broad wavebands in the 2 to 60 Å

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

range with 3 arcsec of spatial resolution and a 48 arcmin field of view. A transmission diffraction grating could be moved into the field of view behind the mirrors to provide spectrographic images. Nearly 35 000 exposures were obtained on 70 mm film from both manned and unmanned missions.

S056: X-ray Telescope. MARSHALL SPACE FLIGHT CENTER *(MSFC):* The instrument was very similar to the S054 x-ray spectrographic telescope, but the metallic filters provided a generally shorter wavelength range of about 6 to 30 Å, corresponding to somewhat higher coronal source temperatures than those of the S054 instrument. The light-gathering area of S056 was about one third that of S054, the field of view was 38 arcmin, and there was no diffraction grating in the S056 instrument. More than 27 000 exposures were obtained on 35 mm film from the manned missions only.

S055: Ultraviolet Spectrometer-Spectroheliometer. Harvard College Observatory (HCO): The instrument was a seven-channel photoelectric spectrometer operating in the 280 to 1340 Å range. Solar rays were reflected off a parabolic mirror onto a reflection grating and then into channel electron multipliers. Seven wavelengths could be simultaneously observed with a spatial resolution element of 5×5 arcsec^2 which could be scanned in a raster pattern of 5×5 arcmin^2 in 5.5 min. Other instrument modes permitted spectral scans over a spatial resolution element or scans at seven wavelengths along a line 5 arcmin long and 5 arcsec wide. Photoelectric data were obtained and stored on a tape recorder on both manned and unmanned missions.

S082A: Extreme Ultraviolet Spectroheliograph. US NAVAL RESEARCH LABORATORY *(NRL):* The instrument consisted of a Wadsworth concave grating which formed spectrally dispersed full-disk images on a film strip. The field of view was 57 arcmin, the wavelength range was 171 to 630 Å, and the spatial resolution was about 2 arcsec. A total of 1023 images were obtained on 35 mm film from the manned missions only.

S082B: Ultraviolet Spectrograph. NRL: The instrument consisted of a parabolic mirror reflecting light through a 2×60 arcsec entrance slit to a predispersing grating, which then reflected it to a main grating and on to a film strip. One setting of the predisperser grating covered the wavelength range 970 to 1970 Å with 0.06 Å resolution and the other 1940 to 3940 Å with 0.12 Å resolution. A slit imaging system allowed the astronaut to observe the position of the slit relative to the white light image of the Sun. Over 6400 spectra were obtained on 35 mm film from the manned missions only.

Of the seven auxiliary instruments, one class permitted the astronaut to do precise solar pointings with coordinates which could be displayed on board and telemetered to the ground. Two separate Hα telescopes with zoom capability and 2 arcsec resolution were used, images of which could be displayed on one of the two 6″ diameter CRT monitors on the ATM control and display panel. The Hα #1 telescope, provided by HCO, was equipped with a film camera which provided pointing information via a superposed reticle that indicated the positions of the coaligned S055 and S082B instruments. Over 68 000 photographs were obtained from Hα #1 on 35 mm film from manned and unmanned missions. Hα #2, provided by MSFC, had a wider field of view but no film camera.

The XUV monitor was provided by NRL and attached to S082B to provide CRT images for the astronauts and ground images for planning solar observing programs. The full-disk images were of 15 arcsec resolution in the 170 to 500 Å range. They were valuable for identifying coronal features and SOLAR FLARES.

Among the instruments used to alert the astronauts and solar mission scientists at JOHNSON SPACE CENTER (JSC) in Houston to solar flares was the x-ray event analyser (XREA), a proportional counter x-ray experiment provided by MSFC which measured x-rays in the 3 to 33 Å range. AS&E provided the photomultiplier exposure counter (PMEC) to detect x-rays in the 0 to 8 Å range and an image disector telescope (IDT) to provide a 3 to 10 Å coarse full-disk image for the ATM CRT. Finally, the radio noise burst monitor (RNBM) provided a continuous measurement of the solar 6 cm flux. In practice the PMEC was used as the flare-warning device, with a threshold set each day for astronaut initiation of flare observing modes.

The ATM scientists were forced by the limited time for astronaut ATM operations and by the number and complexity of the instruments to develop plans for simultaneous operations of ATM instruments. Each scientific problem resulted in a joint observing program (JOP), and each JOP was composed of building blocks (BB) describing the operational sequences of each of the instruments (figure 3). The 13 JOPs of SL-2 evolved into 27 JOPs for SL-4.

Extensive time was required before the mission to train the astronauts in solar physics and the requirements and operations of the ATM experiments. In addition, it was necessary for the scientists and engineers to become familiar with flight operations procedures. An ATM mission control room was set up at JSC which was manned by a scientist and an engineer from each of the five principal institutions around the clock in three shifts. An ATM planning session began each day at noon to plan the next day's operations. Forecasts of solar activity from National Oceanic and Atmospheric Administration (NOAA) personnel and results of current and previous ATM observations were important for the planning. Detailed observing plans were sent up to Skylab that evening. During the night (12 a.m. to 08 a.m.) shift Skylab summary planning was done which resulted in determining how much time (or how many orbits) would be allotted for ATM astronaut operations the following day. Both the summary planning and ATM planning sessions frequently involved contentious negotiations for resources and priorities. Far less planning and support was required for the unmanned periods when only S052, S054, S055 and Hα #1 were operational.

	B	• Point Hα1 at a Hαbright point. • Roll slit for uniform emission. • Maximize DET 1 or 3.
	C	• Repeat B at a second Hα1 bright point.
	D	• Point Hα1 at a relatively dark Hα area • Roll 82B slit for uniform emission.
	E	• Pointing and roll same as 4A. • Repoint 82B slit for uniform emission.

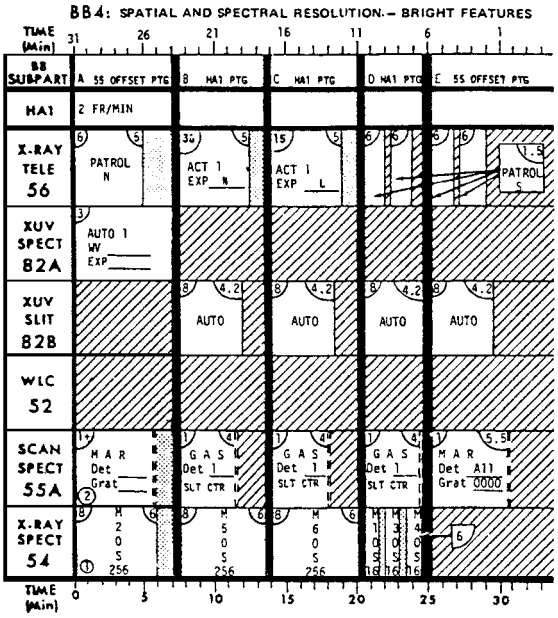

Figure 3. Part of a JOP (top) for active region study and part of one of the BBs (bottom) called for in the JOP. ATM experiments are listed vertically in the BB while time runs to the right, showing various modes and settings for the experiments. From Tousey (1977).

The solar science results

The high-spatial-resolution observations made possible by the ATM pointing system provided significant advances in a number of areas of solar physics. Only after ATM was it clear that coronal structures consisted of magnetic loops. Some phenomena, such as bright points, were completely new. Others, such as coronal holes and coronal mass ejections, had been observed previously, but the clarity and extent of the ATM observations established their basic properties and importance for coronal physics. Earlier ideas, based on observations with coarse spatial resolution, of a relatively homogeneous and slowly varying corona were demolished.

The new results were intensively investigated in a series of three Skylab Solar Workshops in Boulder, Colorado, in the 1970s. The first was devoted to CORONAL HOLES, the second to flares and the last to ACTIVE REGIONS. Each workshop was followed by a published monograph discussing the new results.

Historical perspective on instruments and operations

Solar imaging observations today are obtained from unmanned spacecraft using CHARGE-COUPLED DEVICES (CCDs). Prior to Skylab, solar images from spacecraft were obtained by photoelectrically scanning or rastering the Sun to build up an image. The Skylab mission was a labor intensive transition through a photographic detector stage involving considerable astronaut and ground support involvement. Photographic film, with its instantaneous images over wide fields of view with high spatial resolution, provided a big leap in information content over previous spacecraft observations. Film had, however, several drawbacks. It was a finite consumable which required careful budgeting throughout the mission. It was vulnerable to fogging by heat and radiation. It had a low dynamic range, in contrast to that of the intensities of coronal features being observed. This required that sequences of increasing exposure times be employed to observe both faint and bright features. The S054 x-ray instrument typically used a seven

or eight frame sequence of exposures ranging by factors of 4 from 1/64 s to 64 or 256 s in duration. The film roll had to be carefully developed on the ground, and calibration was always a challenge. CCDs have proven their clear superiority to film for solar observations.

After the Skylab mission, it was generally concluded that the astronauts had played key roles in the success of the mission. The reasons were twofold: (a) they carried out solar observations, and (b) they performed repairs on instruments. Astronauts removed cloth threads from the front occulting disk of the S052 coronagraph and moved a jammed filter wheel into a filter position in the S054 x-ray telescope. They also pinned open experiment doors that had failed shut and replaced failed or troublesome film transport assemblies.

Astronauts functioned well as observers, but they carried out solar observations for only about 23% of the total manned mission periods. The presence of limited film budgets and the need to set the hard-wired switches for experiments on the ATM control panel also mandated a critical role for the crew that photoelectric detectors and computer control of instruments render unnecessary. A similar critical role was accorded the astronauts in the eight-day Spacelab 2 mission in July 1985, but the limited success of that mission indicated the problems of a multidiscipline, limited-duration solar mission with untried instruments. Perhaps the most significant factor in the demise of the crew-operated solar experiments is the great improvement in communications that allows a high degree of control of space experiments from the ground. That capability has obviated the expensive cost of launching and supporting human solar observers.

Skylab did provide us with some visions of the future. Among the viable innovations associated with the Skylab program, we can count the following:

(a) The development of coordinated observing programs among the experiment groups.
(b) A guest investigator program for scientists not part of the PI institutions.
(c) The use of thematic workshops to advance the science from the mission.
(d) The use of calibration rocket flights (calrocs) as a means of instrumentation calibration.
(e) The use of a supporting coordinated ground-based observing program.

Slipher, Vesto Melvin (1875–1969)

Astronomer, born in Mulberry, IN, became director at the Lowell Observatory. He used spectroscopy to determine the rotation periods of several planets, and identified the constituents of their atmospheres. He recorded the first radial velocities of galaxies. The exposure times for these early photographs were as long as a week. The data were extended by EDWIN HUBBLE to discover the expansion of the universe. With the data, Slipher measured the rotations of the spiral galaxies. He supervised the search for the ninth planet, Pluto.

Sloan Digital Sky Survey

The Sloan Digital Sky Survey employs a special purpose 2.5 m telescope located in New Mexico to create a five-color digital map of 10 000 square degrees of sky, to be complete by about 2005. The images will be used to autonomously select one million objects for spectroscopy, via a multi-object spectrograph mounted on the same telescope, yielding redshifts, and thus distances, for each galaxy. A huge number of previously unrecognized quasi-stellar objects and peculiar stars will also be revealed. Although originally motivated by problems concerning large scale structure of the universe, the Survey will constitute a permanent public data bank applicable to a large variety of problems in astronomy, ranging from nearby asteroids to the most distant quasars. The Survey is conducted by an international consortium of ten universities and research laboratories.

Small Astronomy Satellite (SAS)

Series of three pioneering NASA scientific satellites, launched 1970–75. SAS-1, also known as UHURU (Freedom), was the first dedicated x-ray astronomy satellite. SAS-2 was the first satellite to detect gamma rays, and it discovered the enigmatic Geminga source. SAS-3 also carried x-ray experiments.

Small Magellanic Cloud

The smaller of two nearby companions of the Milky Way Galaxy that can be seen with the naked eye in the southern hemisphere sky and which are named after the Portuguese navigator, Ferdinand Magellan. Located in the constellation of Tucana, at a distance of about 190 000 light-years, the Small Magellanic Cloud (SMC) has an angular diameter of about three degrees, about half the apparent diameter of its larger sibling, the Large Magellanic Cloud. It contains about 2 billion stars and has a mass of about one-fiftieth of the mass of the Milky Way Galaxy (about one-fifth of the mass of the LMC). An irregular galaxy (Hubble class Irr I), it has been stretched into an elongated cylinder, some 60 000 light-years long by about 15 000 light-years wide, with its long axis pointing towards our Galaxy, presumably as a result of gravitational tidal forces exerted on it by the Milky Way Galaxy. Although it contains substantially less gas and dust than the LMC, it nevertheless contains significant numbers of HII regions (luminous nebulae), young clusters and hot young stars. The presence of these objects suggests that it has experienced a recent bout of star formation, possibly triggered by a close encounter with the Milky Way that took place about 200 million years ago.

Smart-1

First European Space Agency advanced technology demonstration mission proposed under the Horizons 2000 Science plan. Intended to demonstrate innovative and key technologies for scientific deep-space missions such as solar electric propulsion. Launch is planned for late 2001. Possible targets include the Moon, near-Earth asteroids and comets.

Smith, Harlan James (1924–91)

Astronomer, born in Wheeling, WV, became director of the McDonald Observatory of the University of Texas at Austin. He discovered (with Dorrit Hoffleit) that quasars were variable, making it possible to set limits to their size and probe the mechanisms of their emission. He identified the dwarf Cepheid variable stars. He studied the radio emissions from Jupiter and the other planets, and the influence of the solar wind on them. He was one of the first astronomers to plan ground-based observations in conjunction with space missions, constructing a 107 in telescope at the McDonald Observatory to support planetary space missions. He was an advocate of space exploration both by orbiting astronomical telescopes and by humans on the Moon, using lunar bases for astronomy.

Smith, Sir Francis Graham (1923–)

British radioastronomer, worked on radar during the Second World War, joined Martin Ryle's group at Cambridge and together they discovered the strongest radio source Cassiopeia A in 1948. For his PhD in 1951 he refined the positions of Cas A and Cygnus A. David Dewhirst at Cambridge pointed out that there was nebulosity at the position of Cas A, which proved to be a supernova remnant, and WALTER BAADE and RUDOLPH MINKOWSKI used the 200 in telescope to identify Cyg A as a galaxy. He showed that the fluctuations in brightness of radio sources were due to local effects in the ionosphere and used the Long Michelson Interferometer at Cambridge to measure its electron density. Became professor at Jodrell Bank where he worked on pulsars, discovering the high polarization of their radio emission and worked on their optical identification and period changes. He directed the Royal Greenwich Observatory and built the UK's telescopes on La Palma in the Canary Islands. He was given the honorary title of Astronomer Royal.

Smyth, Charles Piazzi [also Charles Piazzi-Smyth] (1819–1900)

Astronomer, son of an amateur astronomer, Admiral William Henry Smyth, and named after the Italian astronomer GIUSEPPE PIAZZI. Became director of what was then called the Astronomical Institution on Calton Hill in Edinburgh, which evolved into the Royal Observatory, Edinburgh, in a new building on Blackford Hill in the same city. He made an estimate of the amount of heat radiation received from the Moon and studied the zodiacal light. However, he did not distinguish himself in the role of director, being responsible for the neglect of the instruments, and commissioning a telescope that never worked. Moreover, he was obsessed with pyramidology, founded in the mistaken belief that the measurements of the Great Pyramid are of mystical and mathematical significance. He published very successful popular books on this topic but the Royal Society refused to publish his cranky papers and he became the only person ever to have resigned his fellowship, apparently making a ill-judged threat to do so without calculating that his offer would be accepted. After a negative official report on the state of the Calton Hill observatory, he resigned the directorship and devoted the rest of his life to cloud photography in the Lake District. But although this is basically a sorry tale, Piazzi Smyth made one outstanding contribution to the astronomy of Britain and the world. In 1856, he travelled, on his honeymoon with his wife Jessica, to 'Teneriffe' in the Canary Islands and camped on its high volcano, El Teide, investigating Isaac Newton's suggestion that optical observatories would be better sited at altitude. He discovered that he could indeed see fainter stars than with the same telescope in Edinburgh, and resolve closer double stars. Mount Hamilton Observatory was the first mountain observatory set up on the basis of Piazzi Smyth's site-testing expedition, and the Observatorio del Teide and the Observatorio del Roque de los Muchachos on the sister Canary Island of La Palma are direct consequences.

SNC Meteorite

One of a small number of achondritic meteorites believed to have originated on Mars. The letters SNC (pronounced 'snick') stand for the three main classes: *shergottites*, *nakhlites* and *chassignites*. As of April 2000, 14 SNCs had been discovered. The largest at 40 kg is the first known nakhlite, which fell at Nakhla in Egypt on 28 June 1911.

Snel [Snell or Snellius or Snel van Royen], Willebrord (1580–1626)

Born in Leiden, Netherlands, at first studied law but eventually succeeded his father as professor of mathematics at the University of Leiden. He founded the science of geodesy in 1617, when he published *Eratosthenes Batavus*, which developed the method of triangulation for surveying. In 1621 he discovered what became known as *Snell's sine law* of refraction; it was first published by HUYGENS in his book *Dioptrica*. He published on astronomy including on comets; he remained committed to the Ptolemaic theory.

Société Française d'Astronomie et d'Astrophysique

The French Society of Astronomy and Astrophysics (SF2A) (previously SFSA for Société Française des Spécialistes d'Astronomie), officially constituted on 18 November, 1978, includes about 500 French astronomers and astrophysicists. Its basic aim is to induce a better cohesion among the professionals in astronomy and to defend the interest of their research activity.

Since November 1980 a journal has been regularly published in French: *Le Journal des Astronomes Français*. It is sent to more than 800 scientists. Also a regular letter is sent by e-mail, in which information of all kinds concerning French astronomers is given.

The society organizes a meeting every year, in a different French town. In 1999, the meeting was organized in Toulouse, together with the general meeting of the EUROPEAN ASTRONOMICAL SOCIETY (JENAM'99). In 2000 the SF2A meeting was held in Marseille.

Every year, during the meeting, a scientific prize is given to a young researcher who contributed in a major way to the advances of research in astronomy. The prize is sponsored by the society Compaq-France. In 1999 it was given to Francis Bernardeau, for his work about the formation of structures in the primordial universe.

The society also organizes a school every year on a different specialized subject, in the town of Goutelas. The proceedings of these Goutelas Schools are regularly published.

For further information see
http://www.iap.fr/sf2a/.

Software in Astronomy

'Software' is the term used to refer to the programmed sequences of instructions that are executed by a digital computer. Software of some sort is required by any task that involves a computer. Computers first became generally available in the years following World War II, and since then they have become progressively more powerful, progressively cheaper and progressively more ubiquitous. Computers now influence almost all aspects of astronomy: applying for observing time; the scheduling of observations; the acquiring and reducing of data; the final dissemination of data across networks, particularly the internet; even the use of presentation graphics systems when giving talks at conferences.

Software is needed for all of this. In some cases, general-purpose software, such as Microsoft's PowerPoint for presentations, or LaTeX for typesetting, can be used. In other cases, for example the control of a specific instrument, special-purpose software is needed. This has to be written, either by astronomers or by specialist programmers employed by an astronomical institution or university. The production of specialized software is a labor-intensive undertaking, and this provides a continuous incentive to re-use existing software if at all possible. However, there are a number of factors conspiring against such re-use, and how these are overcome may be one of the most important challenges facing astronomical software.

Acquisition and reduction of astronomical data

Most of the specialized software written especially for astronomy is used either for the actual obtaining of data or its subsequent reduction and analysis.

Data acquisition is a question of the control of telescopes, instruments and detectors. Telescopes need to be pointed at their targets and kept pointing at them despite structural deformation, atmospheric refraction and other effects. Their control software can attempt to calculate these effects in advance and allow for them. It can also make use of feedback systems such as autoguiders and—in recent years—active optical systems. Detectors and instruments need to be configured and the data read and recorded, generally with some feedback to the astronomer as to the quality of the data being obtained. Radio observations may involve the control of hardware correlators. All of these aspects need to be coordinated by some higher-level system that may even allow the order of pre-planned observations to be changed in response to atmospheric and other conditions.

Most data reduction has an initial stage, which is essentially the removal of the instrumental effects from the data. In many cases the ideal result will be a calibrated image—a two-dimensional image each element of which is at a known sky coordinate and whose value is an absolute intensity. Alternatively, it may be a calibrated spectrum or set of spectra—each a set of data values covering a known wavelength or frequency range and whose value is again an absolute intensity measurement. There are other types of data, such as time-resolved data, and some measurements may include POLARIZATION and other parameters, but in all cases the ideal is that all instrumental effects have been removed and the result is as the target object produced it. Subsequent processing will depend on the problem the data was taken to solve.

Optical data are usually in the form of images taken by a two-dimensional detector. These may be direct images of an area of sky or may be the images seen by a spectrograph CAMERA, in which case they will contain one or more spectra. These spectra may be distorted, especially when echelle spectrographs are used. Long-exposure CCD images often contain cosmic ray events which can be identified by comparing one or more exposures of the same target field. Images usually require division by a flat field to take out pixel-by-pixel instrumental variations, and linearity corrections if the detector is non-linear. It may be necessary to subtract detector bias values, determined by exposures with no light on the detector, or sky background. For images, techniques such as the construction of median sky frames may be used. For spectra, extraction techniques attempt to trace the spectra and any corresponding sky data and subtract the two.

Radio data, particularly when produced by synthesis telescopes, need more complex processing even to get to a two-dimensional image of a target. CORRELATORS provide the fringe phases from baselines between pairs of antennae, which, once calibrated, are then samples of the Fourier transform of the required image. As a result Fourier transforms are required to obtain an image. The uneven and incomplete sampling in the Fourier domain means that even a perfect point source gives a messy picture with significant side-lobes, effectively convolved with a 'dirty beam' caused by this imperfect sampling. An iterative algorithm due to Hogböm, called CLEAN, is usually used to tidy this up, estimating the dirty beam and successively subtracting it from each source. Further calibration steps, making use of redundant information in the data, can reduce the residual errors.

Data and file formats

Data files are usually passed, on tape, disk or a network, from the data acquisition system at the telescope to the data reduction system to be used by the astronomer.

Being able to transfer information between computer systems is of fundamental importance, but the differences between machines can complicate this. If a 32-bit number is held in four 8-bit 'bytes', is the first byte the most or least significant? Unfortunately, even today both conventions, termed 'big-endian' and 'little-endian' (after the petty squabblers over boiled eggs in *Gulliver's Travels*) are commonly used. Personal computers based on Intel processors are little-endian, SUN Workstations are big-endian. Floating-point formats—the way non-integer values are represented—have also varied in the past, but there is now an IEEE standard for floating-point data and most machines have adopted this.

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

These considerations make it difficult even to write out a single number from one machine in the certainty that another machine can read it. However, for astronomy a much more complicated problem is the question of the higher-level file formats used. A 'file format' refers to the conventions adopted when writing data to a file. An instrument may create a data array of *nx* by *ny* data values, but if all its control software does is write this to a disk file as an image of how it appears in the instrument computer's memory, this will be hard to make use of. At the very least, a program that will read it needs to be able to start by determining the dimensions of the data, so this information needs to be included and some convention is needed for how this is to be done. For practical purposes a great deal of additional information is needed—the name of the object under study, instrumental parameters, time of observation, coordinates of the target object, etc. In the early days of astronomical instrumentation, *ad hoc* formats proliferated, and in many cases the only software that could read data written by a given instrument was the software package that wrote it. The search for a universal file format has elements of the search for the Holy Grail, but it is also an area in which a great deal of progress has been made.

FITS format

It is still the case that most astronomical software packages have their own internal formats. However, in 1981 Wells, Greisen and Harten published a description of FITS (Flexible Image Transport System). FITS defined a set of conventions based on the use of a header prefacing the actual data. This header contained pairs of keywords and values describing the actual data. Additional keywords could be added to provide the ancillary information associated with the image. To get the most out of a FITS file one had to have a reading program that understood the meaning of all the keywords in the header. However, it was possible to write a program that could extract the main data array from a FITS format file even in the presence of ancillary information that the programmer had not anticipated. FITS became and has remained the *de facto* standard for the interchange of astronomical data. Over the years many groups have proposed and implemented and used extensions to the original FITS standard, and some of these have been incorporated into the evolving standard. FITS can now handle multiple images (so can associate error and quality information with a base image, or can handle a set of related images) and can include an arbitrary amount of tabulated data. A standard library of routines for accessing FITS data (CFITSIO) is available from GODDARD SPACE FLIGHT CENTER. FITS provides a good example of the advantages of standardization and the CFITSIO library is a good example of software re-use.

For some purposes it is natural to arrange data items in a hierarchical structure. Hierarchies provide an obvious way of arranging large amounts of related data, and systems exist that provide such an arrangement within a disk file. The Starlink project in the UK uses a hierarchical format called HDS, while the National Center for Supercomputing Applications (NCSA) supports a format called HDF that has a similar philosophy. These formats can handle a greater variety of information than can FITS, but have not attained the almost universal acceptance that FITS has. Most large astronomical software packages can import and export data in FITS format.

Evolution of astronomical software

Until the 1960s, computers were of only limited application in astronomy. In the 1950s early programmable calculating punches and similar devices were used by almanac offices. Although these were programmable, they were programmed using plug boards and the term 'software' was not used in this context. Mainframe computers such as the IBM 7090, introduced in 1959, could run FORTRAN programs and these began to be used for ephemeris calculations. They could also be used to run model atmosphere codes, which involved intense mathematical calculation but which did not require connection to instruments. At that time, observational astronomy made little use of computers and software.

Mini-computers

The emergence of the mini-computer, notably the PDP-8 and PDP-11 series, in the late 1960s and early 1970s meant that it was feasible to provide computerized control systems for the 4 m class optical telescopes then being built. Earlier telescopes, in the main, had relied on the characteristics of the equatorial mount to keep them tracking their targets and on offset guiders to provide a fine correction. Introducing computers made it feasible to model the telescope errors, introduced for example by mechanical flexure, and to correct for them. Computers could also allow for atmospheric refraction, could precess coordinates, could slew the telescope in the most efficient way and could control raster scans. With the advent of computer control systems telescopes began to be judged by how accurately they could set on an object of given coordinates, and how accurately they could track that object without the use of guiders. The Anglo-Australian Telescope (AAT) set the standard for such systems, being able to set with an accuracy of better than 1.5 arcsec when it came on line in 1974. Computerized control system could also handle the more complex control requirements of telescopes with alt-az mounts.

At about the same time, optical detectors were moving into the digital era. Before then, most optical observations had been photographic in nature. While spectra might be scanned by microdensitometers, the output would go to chart recorders rather than being fed to a computer. However, the new electronic detectors such as Wampler's Image Dissector scanner or Boksenberg's Image Photon Counting System, both of which fed data directly into computer memory, could not operate without computers.

On the mini-computers available then, 64 Kbytes represented a substantial amount of memory and hard

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

disk drives were expensive options that held only a few megabytes (2.5 Mbytes was typical). These were '16-bit' machines, using only 16 binary bits to represent memory addresses, giving them a natural address limit of 64 Kbytes, although this could be worked around in some cases. Programming was often done using assembler languages, although FORTRAN was available. Minicomputers could be used for instrumentation because they were sufficiently affordable (for the time) that such a machine could be dedicated to an instrument or telescope. The amount of memory available for such machines was a serious restriction, but they did have very capable real-time operating systems. Portability of code was rarely an issue, and programmers generally felt that their only object was to produce code that would do the required job with the available equipment. Proponents of methodologies such as 'structured programming', which emphasized a clear structure to a program above absolute performance, did not always find a receptive audience until machines became rather faster.

Memory limitations were one reason for the popularity of the Forth programming language. A program written in Forth's somewhat unconventional syntax would be converted into instructions for a 'Forth machine' that had an extensible instruction set—new instructions could be defined in terms of sequences of other instructions. Since this extensibility encouraged the re-use of existing instruction sequences, this made for a remarkably efficient use of memory. The first complete, standalone Forth system was developed by Moore for the Kitt Peak 11 m radio telescope in 1971. Forth became very popular and was used widely for telescope and instrument control and data reduction. As machines gained more memory, however, Forth's efficient use of memory became less compelling an attraction, the freedom it provided could be seen as a liability, and its reputation for making it easy to write code that was very hard to understand began to tell against it.

Data reduction for RADIO TELESCOPES became more complex with the advent of the APERTURE SYNTHESIS telescopes such as the VERY LARGE ARRAY (VLA), because of the need for Fourier transform processing to produce images. At this point, the need for radio-astronomical computing increased dramatically.

Software frameworks

In 1977 Digital Equipment Corporation (DEC) introduced a significant machine for astronomy: the VAX 11/780 was an outgrowth of the PDP-11 line, but it used 32 bits for memory addresses and could swap memory blocks to and from disk to give the impression it had more memory available than was in fact the case (a technique called 'virtual memory'). Such a machine can handle data arrays of many megabytes directly, without having to resort to devious programming techniques. With a 1024 by 1024 pixel CCD producing data arrays of 4 Mbytes per readout (if converted to floating-point form for data reduction purposes), this capability was sorely needed. For most of the 1980s the VAX and its VMS operating system became a *de facto* standard for astronomical software.

The ability of the VAX and similar machines to run much more complicated software allowed astronomical software designers to think more about the 'systems' aspects of what they were writing. An ideal had always been to provide a framework that could be used by any programmer as a basis for a new program, rather than requiring each new program to be written from scratch. For example, a data reduction framework could define the file formats to be used, could define a common command language that could invoke a new program—provided that the new program was written to the framework's conventions—and could allow that new program to interact with other programs. The way parameter values could be specified by the user and passed to a program would be laid down, so that all programs run within the framework would provide the same 'look and feel'. By providing subroutine libraries that could be called by programs written for the framework, it would be made easy to write new programs that would provide new facilities while integrating seamlessly with the existing system.

Data reduction frameworks

Some work on framework systems had started earlier, but the advent of the more powerful machines allowed it to accelerate. Data reduction systems were the obvious applications for such frameworks. Almost all astronomers want to process their data in some standard ways (everyone wants to display data, divide by flat fields, do wavelength calibrations or Fourier transforms, etc) and most then want to apply some specialized processing as well. Ideally, they would use the standard tools provided by a framework—the existing application programs—for the former. Then not only would they write their own programs, using the framework, for the latter, they would make these generally available so that the system would grow. Software re-use of this sort is potentially one of the best ways of reducing the cost of astronomical software. The AIPS system, first developed for the reduction of radio-astronomical data in 1978, was a successful early example of this sort of framework system.

AIPS was written in the first instance to support the new VLA radio telescope. It was designed to be easy to port to different computer systems. It was implemented first on a ModComp Classic and on a VAX 11/780. Written in a standard language (the long-established FORTRAN variant called FORTRAN-66), it had different implementations of the same low-level subroutine interfaces used to conceal differences between machines. AIPS emphasized the need to handle coordinates properly and provided general-purpose image manipulation routines together with the radio-specific operations such as CLEAN.

Data acquisition frameworks

Data acquisition systems were less obvious candidates for the framework approach. An observatory would usually have only a limited number of instruments, and these would be programmed in house. However, even these needed a significant amount of infrastructure. An optical observation might require coordination between the telescope, a detector, a spectrograph, a data display subsystem and a data recording subsystem. Early control systems were often large monolithic single programs that handled all aspects of an observation. In principle, a more manageable structure results from splitting such a system into a number of cooperating tasks each handling one aspect, such as the telescope. It also allows standard parts such as the telescope task to be re-used unchanged in a different configuration of tasks designed to control a quite different instrument.

Although such an approach has compelling advantages in terms of modularity and structural elegance, it requires an underlying framework that can coordinate a number of concurrent real-time tasks (tasks responding within rigid time constraints to external events generated by the instruments they control). This is generally a more complex framework than is needed by a system designed purely for data reduction. An example was the ADAM system designed originally at the Royal Greenwich Observatory in the UK and ported to the VAX at the Royal Observatory Edinburgh. It can be argued that what is required for data reduction is a subset of that required for data acquisition, and a data acquisition framework should be ideally suited for data reduction. The UK Starlink project took this line, and uses ADAM as the basis for its data reduction software.

Workstations, microprocessors and UNIX

The VAX was a multi-user machine, but it was possible to use it for dedicated instrumentation control; its VMS operating system provided, at least nominally, the facilities needed by real-time tasks, such as the ability to insist that physical rather than virtual memory be used for critical program sections, and a task scheduler that should prevent high-priority tasks being blocked at critical times by the more mundane requirements of lower priority tasks. The 4.2 m William Herschel telescope (WHT) in La Palma was controlled by a dedicated VAX system, as was the 2.3 m at Siding Spring in Australia.

At the same time, the microprocessor had started to appear. Microprocessors allowed engineers to design hardware subsystems around dedicated programmable computers. These were often run with 'home-built' operating systems written for the immediate purpose—sometimes without operating systems as such at all. These would usually be programmed in assembler, sometimes in a higher-level language, C. A small microprocessor-based system could be used to provide direct real-time control of a single instrument or part of an instrument. Data acquisition systems could now be built with a machine such as a VAX handling the overall control and processing the resulting data, but using a bevy of microprocessors to provide the tight real-time control needed by the actual instruments.

It is unusual for one computer system to remain dominant for any length of time, and the challenge to the VAX came from the emerging UNIX workstations. The UNIX operating system, as it appeared at first in 1967 on a PDP-7, made little pretence at being a real-time system. Its great advantage was its portability; it was an operating system written not in assembler (as most were, for efficiency) but in C. Moreover, it was made freely available and so became very popular, particularly in university computing departments. This made it an ideal match for the workstations that were being built around the more powerful of the new microprocessors, such as SUN's SPARC and the MIPS processors. These reduced instruction set computers (RISCs) provided a limited set of basic instructions, but were able to run them very quickly. Computers based around RISC processors, almost all of which now run UNIX, are the dominant systems in astronomy at the turn of the century. Unfortunately, different implementations of UNIX still manage to differ, sometimes in quite significant ways.

Recent developments

There are now some common elements to astronomical computing systems. In recent years the trend has been for workstations, almost all running UNIX, to become faster, and almost all are now networked. Instrument control systems generally involve workstations for overall control and on-line data reduction, with dedicated real-time systems based on microprocessors in direct control of the instruments and the telescopes themselves. These microprocessors, often as powerful as the workstations, usually run some real-time kernel system; examples are VxWorks and pSOS. These generally try to provide a programming environment as close to UNIX as possible, but with additional features to support their real-time nature—and with additional limitations imposed by that real-time nature.

Data reduction

A number of data reduction frameworks exist. AIPS continues as the mainstay of radio astronomical data reduction, but is in the process of being superseded by AIPS++. AIPS++ is written using the object-oriented language C++, a descendant of C that supports and encourages an approach to programming where one creates software 'objects' that are capable of performing a number of related functions. This can often be a more natural way to program, possibly because it has analogies to the way tasks in the real world are accomplished by people or groups each specializing in certain tasks, which they perform as requested. For optical data reduction, the dominant framework is IRAF, the Image Reduction and Analysis Facility developed and maintained at NOAO since the mid-1980s (see SOFTWARE: IRAF). IRAF provides a programmable command language and a large and

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

increasing number of applications. Originally, IRAF applications had to be written in its own programming language, SPP, provided in the interests of portability; more recently interfaces to more standard languages have been provided. The UK Starlink project continues to support the use of ADAM for data reduction, and ESO provides MIDAS. However, no such system has gained the level of world-wide acceptance that IRAF has achieved.

There are numerous other data reduction packages in use. A number of programs are built around the commercial IDL system, which provides interactive facilities for manipulating and displaying data arrays. Interactive languages such as Perl and Tcl/Tk are used to produce very flexible programs with easily programmed user interfaces, and Tcl/Tk in particular is used by a number of the larger frameworks. The Glish interactive language, used by AIPS++, is also finding uses in instrument and telescope control.

Data acquisition

The data acquisition software environments used at major observatories are now almost all based on a framework of some sort. This is partly because of the increasing trend to have instruments for telescopes built not by the observatory but by outside institutions, often university departments. In these circumstances, the observatory can get a homogeneous set of instrument control packages only by imposing the use of such a framework—which also makes it easier to write the instrument control software, once the often steep learning curve for the framework has been overcome. Moreover, this allows for much better integration of instrumental software with the overall observatory system, which now tends to take control of aspects such as archiving of data and even observation scheduling. Stand-alone instruments, with isolated one-off control systems, are no longer an acceptable or efficient way to use a large telescope.

There is, however, no dominant instrumentation framework as yet. A number of existing systems are based around a 'database' approach to instrument control, a paradigm where instrumental settings are viewed as database entries. Such entries can be monitored easily to provide user interfaces, especially if a change in a database entry triggers the corresponding actual change in the hardware. This style of operation originated in systems such as accelerators where there are a large number of small items to control. It has more difficulty handing hierarchical systems where there is a natural flow of control with a number of stages overlapping in time. A number of observatories, such as Gemini, have adopted the EPICS database system. A similar system, the commercial RTAP system from Hewlett-Packard, is used by the ESO VLT project. Systems differ in the extent to which this database paradigm (as opposed to more conventional command-based systems where relatively large-scale tasks respond to commands sent by other tasks) pervades the whole system. The VLT has a more conventional command-based layer than does the Gemini system, where commands are implemented in terms of the underlying EPICS database. Other systems, such as the AAO's DRAMA, a descendant of ADAM used on a number of UK-affiliated telescopes, are entirely command based. The Keck telescopes use a system called KTL (Keck Task Library) which is a command-based system that provides interfaces to both EPICS-based and non-EPICS instruments. IRAF is beginning to provide some of the communications facilities needed by data acquisition environments, and these are being used by some instrumentation projects.

Variety and standards

The variety of astronomical software can be a problem for the astronomer looking for nothing more than a way to reduce her data. However, it can be seen as a necessary consequence of a continual search for improved ways of doing things. When there is no perfect solution, and the best solution on yesterday's hardware fails to take full advantage of what is available today, new ideas have to be pursued. Only if these are pursued simultaneously by a number of separate developers will the best solutions emerge. The real problem is to provide ways for such separate developers to take advantage of what others are doing where possible and to avoid unnecessary duplication of effort. The number of *de facto* standards that have emerged is encouraging. For example, although there are a large number of different image display packages available, both Gemini and ESO are using the ESO real-time display package (RTD). Also, almost every astronomical package can read and write FITS format files. The production of standard libraries of routines—a long-lasting example might be the PGPLOT library of routines used for plotting data—can assist here, and this should extend to the re-use of C++ objects, even eventually the production of re-usable software components, such as Active-X controls or Java beans.

Personal computers

Personal computers (both Intel-based systems running a version of Microsoft Windows and to a lesser extent Apple Macintoshes) are used extensively by astronomers, since astronomers have to write papers and give presentations. There are a number of packages aimed at amateurs that do, for example, CCD image processing on PCs, and there are also some excellent 'planetarium' programs available. However, there is little professional astronomical data reduction software available for Windows or Macintosh. There is some use of component software, such as that provided by Active X controls, for small-scale instrument control, but this can be hard to integrate into an overall observatory system. However, the emergence of Linux (a UNIX-like operating system that is freely available and which runs on PCs of both kinds) has made it possible for astronomers to run astronomical UNIX-based packages on their home computers. This has a number of implications for the way astronomers will work in future—many find they have a more powerful machine available at home than they do at work.

Archives and the internet

Software is becoming increasingly important both before observations are made and well after the data are reduced and published. For the VLT, for example, observations need to be planned well in advance using software that generates observation 'blocks' that will be executed much later at the telescope by the control system. The information introduced at that planning phase is associated with the data as they become part of the data archive. That data archive can be thought of as an instrument in its own right, and its store of data can be 'mined' years later, either reducing the need for observations that replicate earlier ones or to provide a long-term study of particular objects (see e.g. SOFTWARE: RADIO PULSAR SOFTWARE).

Making proper use of the huge data archives, particularly those from survey telescopes, is a new challenge for astronomical software (see also SOFTWARE: DIGITAL SKY SURVEYS). A large number of internet web sites now provide access to archival data, survey data, preprints of articles and even journals that are completely electronic in nature. NASA is a good example of an organization that disseminates information widely through the internet, both to professional astronomers and to members of the public. This becomes circular: observation preparation software can obtain from the internet a digitized picture of the sky around a target object and observers can use this to choose the guide stars needed for a new observation, which in turn will eventually be archived and made available.

Bibliography

Few facts are so transient as those relating to computers and software, and there are few conventional publications on the subject. All the various software packages are documented and in most cases both the documentation and the code can be found on the internet. Most of the major observatories have web pages with links to the packages they use and develop. Each year there is a conference on Astronomical Data Analysis Software and Systems (ADASS) whose proceedings are published in the *Astronomical Society of the Pacific Conference Series.*

Software: Digital Sky Surveys

Large digital sky surveys, over a broad range of wavelengths, both from the ground and from space observatories, are becoming a major source of astronomical data. Some examples include the SLOAN DIGITAL SKY SURVEY (SDSS) and the Digital Palomar Observatory Sky Survey (DPOSS) in the visible, the Two-Micron All-Sky Survey (2MASS) in the near-infrared, the NRAO VLA Sky Survey (NVSS) and the Faint Images of the Radio Sky at Twenty Centimeters (FIRST) in the radio. Many other surveys are planned or expected (see also ASTROMETRIC SURVEYS). While most surveys are exclusively imaging, large-scale spectroscopic surveys also exist. In addition, a number of experiments with specific scientific goals, e.g. microlensing surveys for MACHOs, searches for near-Earth asteroids, are generating comparable volumes of data. Typical sizes of resulting data sets (as of the late 1990s) are in the range of tens of terabytes of digital information, with detections of many millions or even billions of sources, and several tens of parameters measured for each detected source.

This vast amount of new information presents both a great scientific opportunity and a great technological challenge: how to process, and calibrate the raw data; how to store, combine and access them using modern computing hardware and networks; and how to visualize, explore and analyse these great data sets quickly and efficiently. This is a rapidly developing field, which often entails collaborative efforts between astronomers and computer scientists.

Broadly speaking, the steps along the way include: obtaining the data (telescope/observatory and instrument control software), processing the data into catalogs of detected sources and their observed properties, calibrating the data, archiving the results and providing the tools for their scientific analysis and exploration.

Survey pipeline software

The actual gathering and processing of the raw survey data encompasses many steps, which can often be performed using a software pipeline. The first step involves hardware-specific data acquisition software, used to operate the telescopes and the instruments themselves. In principle this is not very different from the general astronomical software used for such purposes (see SOFTWARE IN ASTRONOMY), except that the sky surveying modes tend to require a larger data throughput, a very stable and reliable operation over long stretches of time, and greater data flows than is the case for most astronomical observing. In most cases, additional flux calibration data are taken, possibly with separate instruments or at different times. Due to the long timescale required to complete a survey (often many years), a great deal of care must be exercised to monitor the overall performance of the survey in order to ensure uniform data quality.

The next step is the removal of instrumental effects, e.g. flat-fielding of CCD images and subtraction of dark current for infrared detectors. Other than the sheer volume of the data, this process is extremely similar to the usual astronomical observational data reduction techniques.

At this point one does some kind of automated source detection on individual survey images, be it CCD frames, drift scans, photographic plate scans, their subsections, or whatever other 'raw' image format is being generated by the survey. This process requires a good understanding of the noise properties, which determines some kind of a detection significance threshold: one wants to go as deep as possible, but not count the noise peaks. In other words, maximizing the completeness (the fraction of real sources detected) while minimizing the contamination (the fraction of noise peaks mistaken for real sources). Typically one aims for completeness levels of at least 90%, and contamination of less than 10% in the first pass, and typically the source catalogs are purified further at subsequent processing steps.

Most source detection algorithms require a certain minimum number of adjacent or connected pixels above some signal-to-noise threshold for detection. The optimal choice of such a threshold depends on the power spectrum of the noise. In many cases, the detection process involves some type of smoothing or optimal filtering, e.g. with a Gaussian whose width approximates that of an unresolved point source. Unfortunately, this also builds in a preferred scale for source detection, usually optimized for the unresolved sources (e.g. stars) or the barely-resolved ones (e.g. faint galaxies), which are the majority (see DETECTION OF FAINT OBJECTS). This is a practical solution, but with the obvious selection biases, with the detection of sources depending not only on their flux but also on their shape or contrast: there is almost always a limiting surface brightness (averaged over some specific angular scale) in addition to the limiting flux. The subject of possible missing large populations of low surface brightness galaxies has been debated extensively in the literature. The truth is that a surface brightness bias is always present at some level, whether it is actually important or not. Novel approaches to source, or more accurately structure, detection involve so-called multiscale techniques.

Once individual sources are detected, a number of structural parameters are measured for them, including fluxes in a range of apertures, various diameters, radial moments of the light distribution, etc, from which a suitably defined, intensity-weighted centroid is computed. In most cases, the sky background intensity level is determined locally, e.g. in a large aperture surrounding each source; crowding and contamination by other nearby sources can present problems and create detection and measurement biases. Another difficult problem is unblending or splitting of adjacent sources, typically defined as a number of distinct, adjacent intensity peaks connected above the detection surface brightness threshold. A proper approach keeps track of the hierarchy of split objects, usually called the parent object (the blended composite), the daughter objects (the first level

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

splits), etc. Dividing the total flux between them and assigning other structural parameters to them are non-trivial issues, and depend on the nature of the data and the intended scientific applications.

Object detection and parameter measurement modules in survey processing systems often use (or are based on) some standard astronomical program intended for such applications, e.g. FOCAS, SExtractor or DAOPHOT, to mention just a few of the programs often used in 1990s. Such programs are well documented in the literature. Even if customized software is developed for these tasks, the technical issues are very similar. It is generally true that all such systems are built with certain assumptions about the properties of sources to be detected and measured, and optimized for a particular purpose, e.g. detection of faint galaxies or accurate STELLAR PHOTOMETRY. Such data may serve most users well, but there is always a possibility that customized reprocessing for a given scientific purpose may be needed.

At this point (or further down the line) astrometric and flux calibrations are applied to the data, using the measured source positions and instrumental fluxes. Most surveys are designed so that improved calibrations can be reapplied at any stage. In some cases, it is better to apply such calibration after the object classification (see below), as the transformations may be different for the unresolved and the resolved sources. Once the astrometric solutions are applied, catalogs from adjacent or overlapping survey images can be stitched together.

Object classification, e.g. as stars or galaxies in the visible and near-IR surveys, but more generally as resolved and unresolved sources, is one of the key issues. Classification of objects is an important aspect of characterizing the astrophysical content of a given sky survey, and for many scientific applications one wants either stars (i.e. unresolved objects) or galaxies; consider for example studies of Galactic structure and studies of the large-scale structure in the universe (see UNIVERSE: SIMULATIONS OF STRUCTURE AND GALAXY FORMATION). More detailed morphological classification, e.g. Hubble types of detected galaxies, may be also performed if the data contain sufficient discriminating information to enable it. Given the large volumes of data involved in digital sky surveys, object classification must be automated, and in order to make it really useful, it has to be as reliable and objective as possible, and homogeneous over the entire survey.

In most cases, object classification is based on some quantitative measurements of the image morphology for the detected sources. For example, star–galaxy separation in optical and near-IR surveys uses the fact that all stars (and also QUASARS) would be unresolved point sources, and that the observed shape of the light distribution would be given by the point-spread function, whereas galaxies would be more extended. This may be quantified through various measures of the object radial shape, e.g. moments of the light distribution in various combinations. The problem of star–galaxy separation thus becomes a problem of defining a boundary in some parameter space of observed object properties, which would divide the two classes. In the simplest approaches such a dividing line or surface is set empirically, but more sophisticated techniques use artificial intelligence methods, such as artificial neural nets or decision trees (artificial induction software). They require a training data set of objects for which the classification is known accurately from some independent observations. Because of this additional information input, such techniques can outperform the methods where survey data alone are used to decide on the correct object classifications.

There are several practical problems in this task. First, fainter galaxies are smaller in angular extent, thus approaching stars in their appearance. At the fainter flux levels the measurements are noisier, and thus the two types of object become indistinguishable. This sets a classification limit to most optical and near-IR surveys, which is typically at a flux level a few times higher than the detection limit. Second, the shape of the point-spread function may vary over the span of the survey, e.g. due to the inevitable SEEING variations. This may be partly overcome by defining the point-spread function locally, and normalizing the structural parameters of objects so that the unresolved sources are the same over the entire survey. In other words, one must define the unresolved source template which would be true locally, but may (and usually does) vary globally. Furthermore, this has to be done automatically and reliably over the entire survey data domain, which may be very heterogeneous in depth and intrinsic resolution. Additional problems include object blending, saturation of signal at bright flux levels, detector nonlinearities, etc.

The net result is that the automated object classification process is always stochastic in nature. Accuracies better than 90% are usually required, but accuracies higher than about 95% are generally hard to achieve, especially at faint flux levels.

In other situations, e.g. where the angular resolution of the data is poor, or where non-thermal processes are dominant generators of the observed flux, morphology of the objects may have little meaning, and other approaches are necessary. Flux ratios in different bandpasses, i.e. the spectrum shape, may be useful in separating different physical classes of objects.

Survey archive software

Once all of the data have been extracted from the image pixels by the survey pipeline software, it must be archived in order to facilitate scientific exploration. Basically, this data archiving can take one of two forms: raw data access through the Web or some suitable storage and distribution medium (e.g. CD-ROMs or data tapes), or utilization of a database system designed specifically to handle a given digital sky survey archive. The former storage technique, while considerably less expensive, is certainly not optimal for any real analysis, especially for very large volumes of data. On the other hand, using a database system provides

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

significant advantages (e.g. powerful query expressions) limited primarily by how much a survey can afford. Currently, most surveys are accessible from the Internet, whether it is a simple ftp location or a full featured, Web-accessible, query engine.

While certainly flexible and generally easy to establish, Web accessible data are subject to limitations on bandwidth. Despite technological advances which promise to ease such concerns, the rapid growth in available data will continue to swamp available resources. To illustrate this bandwidth problem, for a typical building network (e.g. shared Ethernet at 10 Mbit s^{-1}), it would take nearly a week and half to sift through a terabyte of data (which is the current benchmark for large sky surveys), and this assumes a dedicated bandwidth. Even at fast SCSI speeds (e.g. 100 Mbit s^{-1}), it would take approximately one day to merely move the data of interest.

Each archival center is presented with the challenging problem of storing and serving vast amounts of complex data. Currently the majority of the software written for these applications is in either C++ or Java, while the actual data are transferred via ASCII, FITS or XML. Recently, many of the major data centers have begun to work on sharing knowledge and expertise in order to simplify the development process, as well as improve the overall efficacy of astronomical archives. This work is leading to standards which dictate how archives can communicate with each other, how archives can describe themselves (i.e. their metadata, or data that describes the data), how archives can transfer large amounts of dynamic information, and how sources in different archives can be cross-identified.

In general, the data processing flow is from the pixel (image) domain to the catalog domain (detected sources with measured parameters). This usually results in a reduction of the data volume by about an order of magnitude (this factor varies considerably, depending on the survey or the data set), since most pixels do not contain statistically significant signal from resolved sources. However, the ability to store large amounts of digital image information on-line opens up interesting new possibilities, whereby one may want to go back to the pixels and remeasure fluxes or other parameters, on the basis of the catalog information. For example, if a source was detected (i.e. cataloged) in one bandpass, but not in another, it is worth checking if a marginal detection is present even if it did not make it past the statistical significance cut the first time; even the absence of flux is sometimes useful information!

The two most common types of database management systems used within astronomy are relational-based (where data are manipulated as tables), and object-based (where data are manipulated individually as objects). Each of the two methods have working sites which demonstrate the technology in action (e.g. the 2MASS project uses Informix, while the GSCII project uses Objectivity). In general, relational systems offer more features including third-party add-ons, and powerful query mechanisms due to their dominant position in the business world. On the other hand, object-based systems have shown higher performance and better potential for scaling to extremely large data sets (e.g. CERN is developing an object-based persistence solution to multi-petabyte archives).

Regardless of how the data are actually archived, with the advent of the Internet, essentially all archives are Web accessible. This trend away from tabular or media based archiving produces data sets which are distributed in nature, allowing users and tools equal access to vast amounts of data, which in the past were nearly impossible to efficiently query. As a result, astronomical data are now able to be utilized in a more democratic fashion resulting in uses which the survey institutions did not even imagine.

Scientific analysis and exploration

The end goal of digital sky surveys is to enable scientific investigations. In some cases, the goals are so specific that the best approach is to use analysis software designed and optimized to tackle them, e.g. as in the studies of the cosmic microwave background, in gravitational microlensing experiments, etc. However, most of the modern survey data sets are so information-rich, that a wide variety of different scientific studies can be done with the same data. This entails some general tools for the exploration, visualization and analysis of large survey data sets.

The tools which will be utilized with the new data sets will need to employ cutting-edge techniques from computer science. For example, clustering techniques to detect rare, anomalous or somehow unusual objects, e.g. as outliers in the parameter space, to be selected for further investigation (i.e. follow-up spectroscopy). Other examples include genetic algorithms to improve current detection and supervised classification methods, new data visualization and presentation techniques, which can convey most of the multidimensional information in a way more easily grasped by a human user, and the use of semi-autonomous AI or software agents to explore the large data parameter spaces and report on the occurrences of unusual instances or classes of objects.

The nature of sky surveys and the resulting data sets dictates the kinds of science one may wish to do with them. For example, most surveys would cover a large solid angle, but not go as deep as the typical 'pointed observations'. This, in turn, drives the kinds of data analysis software needed for their scientific exploration. Broadly speaking, the kinds of astronomical investigations for which surveys are well suited include the following.

Multiwavelength astronomy

Combining surveys done at different wavelengths, for a more panchromatic view of the universe. Typically, optical IDs are needed for most of the follow-up work. An obvious example is the optical identification of radio or x-ray sources. A typical basic software requirement is efficient and accurate matching of sources detected in different wavelengths. If positional accuracies and

Dirac House, Temple Back, Bristol, BS1 6BE, UK

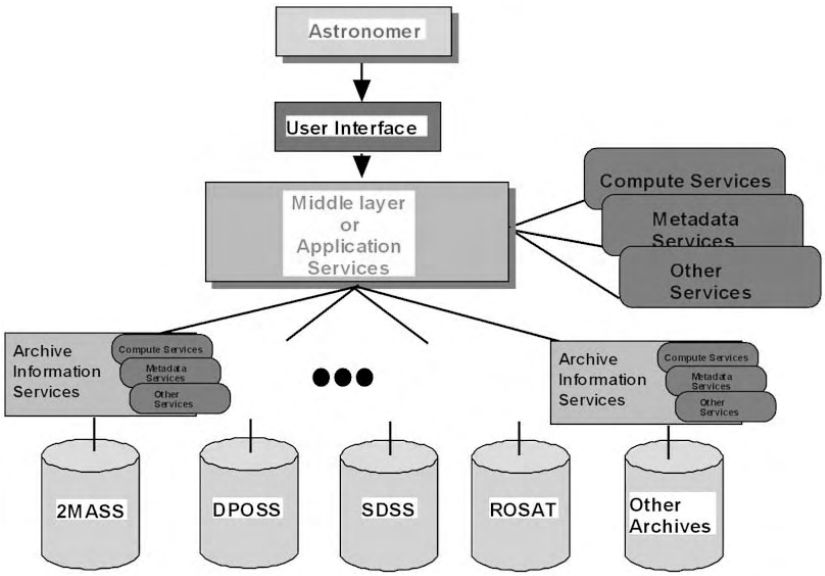

Figure 1. A sample prototype blueprint for the system architecture of a virtual observatory, connecting the scientific users with a multitude of separate digital sky survey archives (schematically represented at the bottom of the picture). The basic task of such a system is to combine large volumes of data from different archives, e.g. through the positional matching of detected sources. Once this is achieved, various other computing services provided by such a virtual observatory may include visualization of data, data-mining, cluster analyis, etc. This system model is predicated on the universal adoption of standards dictating everything from how archives communicate with each other to how data are transferred between archives, services and users.

source densities in matched surveys are comparable this is a relatively straightforward task; however, if either of these two conditions is not satisfied, more sophisticated algorithms may be needed to assign matching probabilities to multiple candidates. These techniques can generally be optimized for certain classes of sources by utilizing as much *a priori* knowledge as possible.

Statistical astronomy

Studies of the large-scale structure (if one detects galaxies in copious numbers), or studies of the Galactic structure (if one detects stars in copious numbers). The sheer numbers of detected sources make the Poissonian fluctuations unimportant, but systematic errors may limit the results. Accurate and uniform flux calibrations and source classifications are essential for such applications, and possible biases should be modeled. In addition, the sheer size of most surveys allows for further subdivision of various analysis (e.g. by morphological or spectral type) for more specific results.

Rare object searches

Searches for rare types of objects or groups of objects, whose frequency of occurrence is so low that huge input source catalogs are necessary in order to find them. This 'needle in a haystack' search is facilitated by the vast number of sources in current surveys (i.e. a one in a million object would appear a thousand times in a billion source survey). Typically such rare objects are found as outliers in some parameter space, e.g. colors: the bulk of 'ordinary' sources (normal stars, galaxies, etc) would form well-defined clusters in the parameter space of observables, and some rare or peculiar types of objects may be found away from them. Unsupervised classification and cluster analysis techniques may be especially useful for this task. This data-mining also facilitates significantly higher efficiencies in performing follow-up spectroscopy of unusual objects. We note that rare objects may belong to known classes (e.g. distant quasars (see QUASISTELLAR OBJECTS: SURVEYS), brown dwarfs, etc), which can be known to occupy some *a priori* determined portion of the given parameter space. Alternatively, there may be previously unknown or unexpected types of objects discovered in this manner.

Future directions

Astronomy finds itself at an interesting time, as several, large-area digital sky surveys are currently under way. In the future, the number of such surveys, as well as the wavelength coverage, will only continue to increase, providing temporal as well as spatial coverage of the sky. This flood of data necessitates a new approach to data handling—a virtual observatory (see figure 1). Individual surveys are important in their own right, but the federation of multiple, cross-wavelength digital surveys provides a tremendous opportunity to truly quantify the origins of stars, galaxies and the universe itself.

This future situation provides the opportunity to adopt a new research paradigm for studying the heavens, as the ability to perform cutting edge research will not be

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

restricted to those fortunate enough to have access to the best facilities. Instead, anyone who has the diligence and ability to sift through the avalanche of data can perform novel science.

Bibliography

The field of large digital sky surveys, the related software methodologies, and the new astronomy they enable are developing very rapidly as of this writing (late 1999). There are thus no standard texts or reviews, and whatever articles do exist tend to become obsolete very quickly. Probably the best way to find more up to date information is through the World Wide Web (and the interested reader will know how). While many Web sites can be somewhat ephemeral, we suggest one which will provide a number of useful links in this field, and which we hope will be active throughout the useful shelf life of this encyclopedia: `http://www.digital-sky.org`

Another possibility is conference proceedings on this and related subjects, e.g. the series of volumes on 'Astronomical Data and Software Systems', published by the Astronomical Society of the Pacific in their conference series. A number of useful papers can also be found in

Software: IRAF

IRAF, the Image Reduction and Analysis Facility, is a large software system used primarily for the reduction and analysis of optical and infrared data from ground- and space-based observatories. The principal IRAF software distributions provide an integrated collection of standard data reduction packages for all instruments operated by the National Optical Astronomy Observatories (NOAO) and the Hubble Space Telescope (HST). Many other observatories use IRAF for processing data from their own telescopes, often providing customized 'layered packages' tailored to reduce data from their instruments. IRAF is also used extensively at the telescope for data acquisition and quick look and by many individuals around the world for general astronomical data reduction and analysis.

Historical perspective

In the years leading up to 1980, data processing at KITT PEAK NATIONAL OBSERVATORY (KPNO) was performed on a CDC Cyber-series computer, a classical mainframe system with computer operators and batch submission of programs using decks of punched cards. To this was connected the pioneering IPPS interactive picture processing system. This consisted of some custom in-house-developed hardware and software used to connect a Tektronix storage scope terminal and a Comtal image display to the Cyber mainframe. Revolutionary for its time, this combination permitted interactive use of the Cyber mainframe for program development and image processing. The Tektronix storage scope terminals and Comtal image display provided interactive vector graphics and image display capabilities. A menu-based system provided the main user interface.

Applications for the old IPPS system were written in Cyber Forth, a locally developed variant of the Forth programming language, and CDC Fortran, used for numerically intensive functions. The IPPS system operated for approximately 10 yr, and was one of the most advanced image processing systems in the world at the time.

In the 1970s the DEC PDP-11 minicomputer appeared on the scene. This was followed shortly by the legendary VAX minicomputer. The VAX was quickly adopted for data processing by astronomy worldwide. These new minicomputers were interactive systems, putting the end-user in control, and would soon doom the batch-oriented mainframe to oblivion. The dominant operating system for the VAX at the time was VAX VMS, which commanded a very strong following from most of the scientific users at the time. A handful of software developers, however, including a small group at Kitt Peak, were excited about a new operating system called Unix, and the new language it was written in, the C programming language.

The transition from the mainframe to the minicomputer sealed the fate of the old IPPS system. The combination of custom hardware and custom software used to build the IPPS ensured that the IPPS was a one-of-a-kind system, the only IPPS installation in the world, and that virtually all of the effort which went into building this system would be lost when the technology it was based on became obsolete. With the coming of the minicomputer, it was time to build a new image processing system to replace the IPPS.

Around 1980 Kitt Peak undertook a study of the existing astronomical data analysis systems of the time (AIPS, Starlink and others) and eventually concluded that a new system was needed to serve the needs of KPNO. The developers were determined that this time around the system would be put together in such a way that the many years of effort spent developing applications software would survive the technology it was based on. To ensure this the system would be both portable and device independent, with controlled interfaces to all external services. Everything learned with the IPPS about interactive graphics and image processing would be preserved in the new system.

The little-known (at the time) Unix operating system would be the primary development platform for the new image processing facility, but the software would be portable and would be supported on VMS and other operating systems from the beginning (in addition to VMS there were subsequent ports to other now extinct operating systems, e.g. from Data General and Perkin Elmer). Two new VAX minicomputers, one running Berkeley Unix and the other VMS, were purchased for developing the new image processing system. Graphics and image display capabilities were provided by DEC VT100/VT640 graphics terminals and an IIS image display.

Development of the IRAF system began at KPNO in Tucson in 1981. By 1984 the basic system framework, command language and a few of the core applications packages were complete. The SPACE TELESCOPE SCIENCE INSTITUTE, after its own internal review of existing systems, adopted IRAF as their data processing framework in 1984 and completed the initial VMS port within the following year. This began a major collaboration between ground- and space-based astronomy which continues to this day, providing users of both communities with a consistent, integrated data processing capability which can be used for both types of data. By the mid-1990s about half of all IRAF software had been contributed by the space science community.

In the late 1980s workstations appeared on the scene, led by Sun, which was just another small workstation vendor in the early days. Following a trip to Silicon Valley to visit Sun, MIPS and other early workstation vendors, Kitt Peak chose to go with Sun. This eventually proved to be another in a series of fortuitous choices for IRAF and NOAO.

The workstation was a major development because it provided a high-resolution bit-mapped screen which could be used to run a windowing system. This was a great boon to scientific data processing because one could use this to implement custom graphics and image processing visualization tools in software (see also SOFTWARE IN

Dirac House, Temple Back, Bristol, BS1 6BE, UK

ASTRONOMY), and every workstation could have its own integrated image display capability. IRAF developed one of the earliest software image displays during this period, the imtool display server for the now obsolete Sunview window system (which pre-dated X). A companion program gterm provided interactive vector graphics. With the subsequent wide adoption of the workstation and the development of the X window system, this was followed by the development of SAOimage by SAO, the X11IRAF tools from IRAF and many other data visualization tools from various sources in the years to follow.

The appearance of the workstation on the world astronomy scene had another big impact: these new systems ran the Unix operating system almost exclusively. Although DEC would later develop VMS-based workstations such as the VAXstation, this meant the beginning of the end for the VMS operating system as a major platform for astronomy software. Some years later the PC would evolve to the point where it was the equal of the workstation. With the PC came the open source Unix-based operating systems such as FreeBSD and Linux, further sealing the fate of proprietary systems like VMS.

By the late 1990s the IRAF system, now approaching 20 yr in age, was a mature system in wide use throughout the world. IRAF had survived a very turbulent period in the evolution of computers and computer software spanning at least three major eras from minicomputer to workstation to PC. Approximately 200 man-years of software development had been invested in IRAF and its applications. By the end of the decade attention was turning to the evolution of the IRAF system itself. A new system framework was needed to take full advantage of new software technology and to permit better use of the wealth of non-astronomy software now available. Research and development leading to this new framework got underway in the late 1990s, aided by several grants from NASA.

The challenge facing IRAF in 2000 as we start into the new decade is to upgrade the foundations of the system even while it is still in use, to bring the system up to date with the latest technology, while preserving the many years of work invested in developing and refining the current wide range of science applications.

System structure

IRAF is not a program, but rather a large integrated software system. Included are a system framework upon which all the other software is based, an integrated programming environment, standard user interface software such as a command language and graphics and visualization tools, and a great variety of applications software. The applications software is organized into packages of logically related tasks.

An IRAF task is an individual program, designed to perform some specific data processing function. A parameter set controls the operation of each task. Tasks may be either simple batch-oriented tasks or interactive tasks which use keystroke, text, vector graphics or image display capabilities to interact with the user during execution. IRAF tasks are normally run interactively from within the IRAF environment, but most tasks may also be called at the host level, e.g. for integration into an external data processing system. IRAF tasks are pure computational modules; where user interaction occurs, the user interface is provided externally by separate user interface modules in the system framework which communicate with the IRAF task at runtime using messaging.

All the IRAF software is integrated into a single system, but all of the applications packages and tasks, and most of the system modules such as the command language interpreter and the visualization tools, are modules which can easily be replaced or substituted. This flexibility is the chief reason that so many institutions have been able to extend IRAF to process their own data, or otherwise integrate IRAF into their local data processing systems. Every IRAF installation is unique, consisting of only those packages which the user has obtained and installed in the system.

From an architectural point of view IRAF consists of a host system interface (HSI), which includes all the system dependent code, and the portable IRAF system, which includes most of the system framework and all applications. The portable code is identical on all IRAF platforms, including all build files; there are no 'ifdefs' or other system-dependent features in the source code or build files. In the runtime system all binary object code and executables are segregated from the rest of the system into 'bin' (binary) directories. A single IRAF installation can simultaneously support any number of architectures, or target platforms; every major class of platform must, however, have a separate HSI.

Applications

An IRAF installation consists of the system framework and the applications packages and tasks installed in the system. As we noted earlier, IRAF tasks (programs) are organized into packages of logically related tasks. Above this there is one additional level of structure, collections of logically related packages. Chief among these are the core IRAF packages and the standard astronomical data reduction and analysis applications developed by NOAO and included in the standard IRAF release. In addition there are many external or layered packages which may be separately obtained and installed in IRAF. Finally there are many individual programs, including user-written Fortran or C (IMFORT) programs, which have been developed by users primarily for their own use. It is this broad collection of IRAF science applications, many of which were contributed by the community using IRAF, which more than anything else has made IRAF such a successful and widely used system.

Core system

The core IRAF packages are generic system packages providing standard facilities for importing and exporting

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

data, general image processing, graphics and image display and data visualization, and user interaction including the IRAF command language (CL), as well as facilities for software development.

Table 1. Core IRAF packages.

dataio	Data format conversion package
images	General image processing package
language	The command language itself
lists	List processing package
local	The template local package
obsolete	Obsolete tasks
plot	Plot package
proto	Prototype or interim tasks
softools	Software tools package
system	System utilities package
utilities	Miscellaneous utilities package

The major packages in the core IRAF system are listed in table 1. Each of these packages contains many tasks. The images package, for example, contains approximately 100 tasks which provide facilities for image filtering, image matching, fitting functions and surfaces, geometric corrections, coordinate manipulation, and general image manipulation. Altogether the core system contains three or four hundred tasks.

Astronomical applications

The standard IRAF distribution also includes a suite of packages for the reduction and analysis of optical and infrared astronomical data called the 'NOAO' packages (table 2). Although these packages include special support for reducing data from the NOAO instruments, most of the packages therein are general enough to be applied to data from similar instruments outside NOAO. Packages are provided for reducing both image and spectral data, as well as standard astrometric, photometric and spectroscopic data analysis. All told the NOAO packages contain about 1200 individual tasks.

Layered packages

Layered or 'add-on' packages are optional applications packages which may be separately obtained and installed into IRAF. Once installed, layered packages are no different from the standard packages included in the IRAF distribution. The NOAO package is actually a layered package itself, even though it is included in the standard IRAF distribution.

Many layered packages have been developed for IRAF, enough so that it has been difficult to track them all. It is hard to be fair in listing layered packages, but a few of those in use at NOAO are listed in table 3.

Table 2. NOAO packages.

artdata	Artificial data generation
astrometry	Astrometry package
astutil	Astronomical utilities package
digiphot	Digital stellar photometry
focas	Faint object classification
imred	Image reductions package
nobsolete	Obsolete tasks to be phased out
nproto	Prototype–interim tasks
observatory	Observatory database
onedspec	One-dimensional spectral analysis
rv	Radial velocity analysis package
surfphot	Galaxy isophotal analysis package
twodspec	Two-dimensional spectral analysis

Table 3. Miscellaneous layered packages.

arcon	CTIO Arcon CCD data acquisition
color	RGB color image composition
ctio	CTIO miscellaneous tasks
dimsum	IR image reductions
euv	EUVE extreme UV reductions
finder	ST guide star catalog astrometry
ftools	HEASARC FITS tools package
grasp	GONG helioseismology package
ice	KPNO/Steward ICE CCD data acquisition
mscred	CCD Mosaic image reductions
nso	National Solar Observatory reductions
rgo	Royal Greenwich Observatory reductions
steward	Steward Observatory reductions
stsdas	Hubble Space Telescope reductions
tables	STScI tabular data format package
xray	SAO x-ray data analysis package

The most notable of the layered packages are the tables and stsdas packages from STScI, which provide extensive facilities for reducing HST data as well as many other generally useful IRAF tasks. The xray and ftools packages also provide many generally useful IRAF tasks. The ice (IRAF Control Environment) package is widely used for CCD data acquisition into IRAF. The mscred package from NOAO is used to reduce data from wide-field CCD mosaic imagers. Other major packages are available from outside groups such as Starlink in the UK and ESO/ECF in Europe.

If we were to add them all up, there are probably a few hundred IRAF packages in all, containing several thousand tasks in total. New IRAF packages are constantly under development.

Graphic and image display

Interactive graphics and image display has been an integral part of IRAF since the earliest days. Although these capabilities are built into IRAF, the actual graphics and image display servers are replaceable components which are distributed separately from the main IRAF distribution. NOAO currently supports a separate product called x11iraf which includes the graphics and image display servers xgterm (basically xterm but with vastly more powerful graphics) and ximtool, a powerful multiframe image display server. The Smithsonian Observatory (SAO) provides additional image display servers which can be used with IRAF, most notably SAOimage and SAOtng. Data interaction is a vital

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

part of IRAF and new facilities are continually under development.

In addition to basic graphics and image display, IRAF includes capabilities for integrated application graphical user interfaces, or GUIs. The system support for these GUIs is included in x11iraf. The actual GUI applications are essentially standard IRAF tasks, with additional messaging capabilities used to link the computational application with the external GUI. This allows the GUI technology to evolve without greatly affecting the science software at the heart of IRAF.

Data formats

The fundamental data objects in IRAF are the image and the table. Logically, images are N-dimensional pixel arrays with an associated image header containing keyword = value attributes describing the image. Images may be complex objects, including associated information such as pixel masks or world coordinate systems describing the mapping of an image onto the sky, or a spectral dispersion. Examples of subclasses of images might include direct images of the sky, spectra or variance arrays. Observations are composed of one or more logically associated images and auxiliary data objects such as tables or other associated information.

IRAF uses FITS for all archival data. Internally IRAF supports a number of runtime image formats used for various types of data. Each image format has a corresponding image kernel in IRAF, which maps the physical or external data format to the logical image data model used in IRAF.

The currently supported IRAF runtime image formats are summarized in table 4. All of these are pixel (raster) image formats except the qpf format, which is a sparse event list used for event-counting detectors. The pixel list image format stores typical image masks in a highly compressed internal format. Most IRAF applications support only the abstract image model defined by IRAF and will work with any of these image formats.

Table 4. IRAF runtime image formats.

oif	Native (original) IRAF image format
fxf	FITS image format
plf	Pixel list image format
qpf	Event data format
stf	HST GEIS image format

Many additional image formats can be used, but a separate image format conversion is required before the image can be used within IRAF. For example, the PC image formats such as GIF and TIFF can be used with an extra data conversion step (see the dataio package).

Special applications

Data acquisition

In addition to conventional data reduction and analysis, IRAF is also used at the telescope for data acquisition and quick look. Using IRAF for data acquisition allows a single familiar environment to be used for all data interaction both at the telescope and at the observer's home institution.

The ice package (IRAF Control Environment), an IRAF layered package, provides integrated control of a detector, instrument and telescope, allowing various types of exposures to be taken with the observation written directly to an IRAF image file at the end of the exposure. Automatic display, postprocessing and archiving of newly acquired images are supported. A more specialized package ccdphot is available for digital aperture photometry with CHARGE-COUPLED DEVICES (CCDs).

More recently the Mosaic Data Handling System has been developed for the acquisition and quick-look processing of CCD Mosaic images (or single-frame CCD images). The companion IRAF package mscred provides for the reduction of Mosaic data. The Mosaic DHS system is component based, using messaging to connect the components and a data feed component to interface to an external detector subsystem and feed data to the DHS. A data capture agent captures Mosaic data and writes them to disk as multi-extension FITS files. Real-time image display and quick-look data interaction capabilities are also provided.

Pipeline processing and archiving

IRAF has long provided standard data reduction packages for a wide range of instruments. In the classic IRAF system data is reduced by running a reduction task or imred (image reduction) CL script on a list of unprocessed images. Some interaction is typically required to reduce the data, especially for spectral data.

More recently an automated pipeline processing facility has been added. A pipeline manager executes the pipeline, driven by an externally defined rule-based pipeline script. External pipeline modules (IRAF tasks or other programs) perform all the actual processing operations. The pipeline manager continually loops over the data set, classifying objects by type and applying processing rules to move data through the stages of processing defined by the user-defined pipeline being executed. The pipeline manager has the ability to run a number of tasks concurrently, on the same host or on a set of cooperating hosts. The parallel processing capability allows this scheme to be scaled up to handle very large data sets.

The automatic pipeline processing capability can be combined with a database system to generate a data archive. In general, whenever an automated pipeline is set up to routinely process data for a particular instrument, it is desirable to go one step further and create an online archive of the data products. If a pipeline is set up and the data are put online, IRAF provides an integrated framework for all data handling from acquisition and quick look at the telescope, through pipeline processing, to interaction with the processed data from the online archives.

Future developments

The framework for a new IRAF system is being prototyped in the Mosaic Data Handling System and the automated pipeline processing facilities discussed in the previous sections. A related NASA-funded project called Open IRAF is adding a multilanguage programming development capability to IRAF, allowing applications to be written in a number of standard compiled or interpreted languages. Other projects are underway to add advanced GUI capabilities and to interface modern scripting languages such as Python and Tcl to IRAF.

The new framework will be component based, using a message bus to connect the components. The system framework will provide standard components for application scripting, GUI presentation, data visualization, parameter editing, online help and the like. Standard data service components based on distributed shared object technology will be used to provide efficient shared concurrent access to data objects such as images or tables. Applications will be assembled from custom compute components which implement the numerical or science algorithms, combined with mostly standard user interface components for user and data interaction. An interpreted script written in one of the supported scripting languages, executing in a script language component on the message bus, will tie the components together.

The new system framework will be inherently distributed since the message bus will allow components on different hosts to interoperate and since distributed shared objects will allow data objects such as images to be simultaneously accessed by multiple components or applications. Including a capability to directly access images and tables stored in local or remote data archives will allow applications written within the new framework to be used for data mining of archival data.

Ultimately the technology developed by these projects will be used to rebuild the framework of the existing IRAF system. Although the IRAF framework and the major user interfaces will be almost completely new, the existing science applications (most compiled tasks) are expected to migrate to the new framework almost unchanged. This will give us a modern new IRAF system while preserving most of the 200 or so man-years invested in the current science applications.

Availability

IRAF is available for most major Unix-based platforms, including both workstations and PCs. A Windows port is possible but does not yet exist. VMS has been supported for many years, but support will be dropped in versions of IRAF beyond V2.11. The set of supported platforms varies from year to year; check the IRAF web pages (http://iraf.noao.edu, or any mirror) to determine whether support is available for a particular platform.

A typical IRAF installation requires a minimum of 50–150 MB of disk space. If some of the larger layered packages are installed, or an installation is configured to support multiple target architectures, the space required can be several times larger. The largest installations, including the most common layered packages and supporting several target architectures, can require a gigabyte or more of disk space.

IRAF is freely available via download over the internet, or a mailed CD-ROM distribution can be obtained from NOAO for a nominal fee.

Software: Radio Pulsar Software

Software used to process radio pulsar data is almost all written in Fortran, C and C++ and runs mainly on UNIX platforms. The size of the user base is such that most of the major groups have their own home-grown solutions to what are very similar problems. However, there are generic features in the software used in the discovery, timing and understanding of the statistical properties of PULSARS.

When the first pulsars were discovered in 1967, computers were not common in radio observatories. Now they play an essential role in the discovery, timing and analysis of pulsars as well as in Monte Carlo simulations that enable us to understand the population. In the 32 yr since the discovery of pulsars we have witnessed an exponential growth in the power of computers with the speed at which they are able to perform calculations doubling every 18 months or so. This has made it possible to undertake large-scale surveys of the Galaxy for pulsars where over a terabyte of information has been recorded and processed. In the future real-time processing of the Nyquist-sampled electric field will be possible for ultra high-precision observations of radio pulsars. At the end of this article a number of WWW (world-wide web) links are given to assist the reader to download software and use online resources (see also SOFTWARE IN ASTRONOMY).

Pulsar searching software

There is no standard pulsar search software used by groups around the world. This is due in part to the fact that most observatories have their own data acquisition systems and so the format of pulsar search data differs. There is also the fact that most astronomers are trained in physics, not computer science, and the flexibility of the software is not always what it could be. Search codes often take a long time to perfect, and, once this is achieved, the source code is rarely distributed. This would mean providing adequate documentation, which is a chore, and there is an implied responsibility that the code is bug free. In my experience, most groups are more than happy to provide mature codes which address most aspects of pulsar astronomy provided that they are not expected to provide a 24 h support line and that the final responsibility for published material lies with the authors of the paper, not the authors of the software.

Almost all pulsar search codes operate on a two-dimensional (2D) data array of time and frequency samples. Because of interstellar pulse dispersion, a large number of frequency channels are required to prevent dispersion reducing sensitivity to radio pulsars. Multichannel filterbanks are the most commonly used data acquisition system, but in the past autocorrelators have been used to form filterbank data and in the future it is possible that searches will record the electric field directly to obtain the ultimate frequency resolution to improve sensitivity.

There are two basic methods of processing these data. The first is to dedisperse at several hundred different trial dispersion measures, perform a fast Fourier transform (FFT), look for spikes, and progressively sum harmonics until 32 or so are added, looking for significant peaks after each harmonic sum. A list of candidates can then be formed, and either the raw data folded at the period and dispersion measure corresponding to the peak to explore the temporal and frequency structure of the candidate, or, as some groups do, just taking note of candidates well above the noise. The alternative is the 2D FFT method, which is faster computationally, but has a more complicated harmonic summing algorithm. Pulsars appear as a series of harmonics equally spaced in the 2D FFT. To be efficient, this requires at least enough random access memory (RAM) to accommodate the 2D FFT. For the Parkes 70 cm all-sky survey this would have been $256 \times 512 \times 1024 \times 4 = 512$ megabytes (MB) which is too large for most typical workstations (in early 1999). At Parkes, larger bandwidths are possible in contrast to most other observatories and the number of channels is particularly large. At Arecibo and Jodrell Bank, it is becoming much easier to fit the search data into RAM and process the search data very quickly. In a recent survey, the Princeton group used the 2D FFT method and reported an increase in processing speed of a factor of 3; see Camilo *et al* (1996).

Unfortunately, the major headache for pulsar astronomers is the eradication of periodic interference from their datasets. Almost all of the recent software developments in search software, at least in our group, have been aimed at eliminating man-made signals which mimic pulsars. One can do this in a number of ways, but it is customary to run through all of the data in a quick pass and find periodic signals that are present in a very large number of pointings and could not possibly be pulsars. Very effective filters can then be implemented in software.

It is wise to fold the original data at the period of the candidate pulsar using the best dispersion measure (DM) and view the pulse profile as a function of both time and frequency. This can eliminate a lot of interference which is often narrow band in character or is not a pure tone, sometimes referred to as having a low Q. The only way to confirm that a source is really a pulsar, however, is to re-observe it.

Pulsar timing software

Once found, a great deal of science can often be deduced from regular observations of pulsars. By cross-correlating the average profile with a standard template, topocentric arrival times can be deduced and fitted to a simple timing model of a pulsar. The model includes such basic parameters as the position in the sky, DM, period and period derivative, from which most of the physical parameters of a pulsar are derived.

When a binary pulsar is discovered it soon becomes apparent that additional parameters are necessary to adequately describe the arrival times. The normal

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

procedure is to obtain as accurate a measure of the pulsar's apparent period as possible at several different epochs and then to perform a least-squares fit to the periods for a Keplerian orbit using a program such as fitorbit, originally written by Brinklow and Lyne at Jodrell Bank. The mathematical foundation of fitorbit can be found in Smart (1977). A similar program 'binfit' was developed by the Princeton pulsar group and is probably more portable. Once several orbits have been observed a first-order fit is usually sufficient to attempt a timing solution with a timing program such as TEMPO.

TEMPO is the most widely used pulsar timing program, currently maintained by the Princeton group and the Australia Telescope National Facility and freely available from the WWW. Numerous authors have made contributions to this program over the years and it has recently undergone extensive revisions. The program runs under LINUX, as well as on SUN workstations and COMPAQ's Digital Unix, and ports have been made to SGI and HP. The only issues to address when attempting a new port are usually byte swapping and the record length of Fortran records.

TEMPO is capable of taking an input pulsar model and list of arrival times and fitting for almost any reasonable parameter. Taylor has introduced detailed support for a variety of models of relativistic gravity and TEMPO was used to time the celebrated 'Hulse–Taylor' (Hulse and Taylor 1975) binary pulsar to a high degree of accuracy which ultimately led to the awarding of the 1993 Nobel prize for physics (see RADIOASTRONOMY).

TEMPO was originally written in the era of punch cards, and for a long time it demanded input parameters in a very strict format in the first six lines of the input file. The top line was a series of 1s and spaces and it was necessary to learn which parameter occupied which column if you wanted to fit for it. Although black belts in TEMPO would not have it any other way, to beginners this proved an impediment to mastery of the program. In the latest revision (version 11) there is a new user-friendly input structure, which is free format and much easier to use.

TEMPO also has the ability to produce an ephemeris suitable for reducing gamma-ray observations made with the COMPTON GAMMA-RAY OBSERVATORY (CGRO) and has a very useful facility to create a polynomial description of a pulsar's topocentric period and phase at any given epoch. This is often used when observing to fold incoming pulsar data at the correct rate to form a nice sharp profile with no smearing.

Pulsar database programs

The new TEMPO input format is identical to the most widely used pulsar database program PSRINFO, developed by Harrison at Jodrell Bank in the early 1990s. The source code now resides at Swinburne University of Technology and has been expanded. This is one program which is freely available with a web interface, and it is possible to interrogate the catalogue online and also create publication quality plots of the pulsar population using PSRPLOT, a program written by Hughes at Swinburne. PSRPLOT uses PSRINFO to retrieve information from the catalogue and has the ability to select populations of pulsars based on several different criteria. The user can request a gif or Postscript version of the plot and a list of pulsars and parameters is provided to the user.

PSRINFO can also create an ephemeris file suitable for input straight into TEMPO, and it is therefore easy to generate polynomial coefficients for observing with a script. PSRINFO can also access the database for specific pulsars or provide lists of parameters. The source code is available on request from Swinburne.

PSRCAT is another catalog program which is less flexible than PSRINFO but has nice formatting abilities when preparing catalogs for the literature and is maintained at Princeton and the Australia Telescope National Facility by Taylor and Manchester.

The European pulsar community provided one of the most sensible advances in pulsar astronomy by standardizing their data into one format. Details of the format are freely available on the WWW. This is probably a sensible standard to follow for new groups as the software to read this format and manipulate it is available from the web site. One of the most useful resources on the web is the European pulsar network's database of pulsar profiles. There are literally hundreds of pulsar profiles nicely indexed and these form a valuable resource. There are numerous mirror sites around the world.

Coherent dedispersion

Pulsar signals are dispersed by the ionized interstellar medium and this smears the observed profiles of radio pulsars. The most common method to minimize this dispersion is to build a multichannel filterbank or CORRELATOR system as the smearing is proportional to the filter width. However, for the fastest pulsars, this is often insufficient to prevent a large amount of pulse dispersion within a single frequency channel.

In their 1975 paper, Hankins and Rickett describe in some detail a method for removing the effects of dispersion exactly by recording the electric field in the antenna at the Nyquist rate and 'coherently dedispersing' the data. This involves filtering the complex data using effectively the inverse filter to that of the interstellar medium in a deconvolution process that gives the highest time resolution possible. At several major observatories around the world coherent dedispersion software is being written. Even in 1999 coherent dedispersion is difficult, because, with any reasonable bandwidth, the amount of data is immense. For a 10 MHz bandwidth and two-bit sampling, observers are required to record 10 MB s^{-1} of raw data and take this away for processing. The Caltech–Parkes–Swinburne Recorder (CPSR) is located at the Parkes observatory and it is capable of recording 20 MB s^{-1} continuously using four DLT7000 tape drives and six 9 GB disks for destriping the data for convenient post-processing. Similar systems are in place at Arecibo, Jodrell Bank and Westerbork but with more modest bandwidths.

The software used for this processing has to be able to unpack the two-bit numbers, filter them and fold the data at the topocentric pulsar period. Although this sounds easy, the major problem is that in a week-long run the amount of data recorded can be 10 MB s^{-1} for 7 days, which is 6 TB. Just to read these data back on a single DLT7000 takes 14 days. On the Swinburne supercomputer, our coherent dedispersion software takes 64 times real time to process a 20 MHz band on a single processor. Hence it is imperative to ensure that the code has a high degree of parallelization in it or that one can run on multiple processors. Groups thinking seriously about commencing coherent dedispersion timing programs should think carefully about the computer power required. As computers become more powerful this will be less of a consideration.

Coherently dedispersed data have a time resolution of $1/B$, where B is the observing bandwidth. It therefore makes it possible to study the pulsar magnetosphere on submicrosecond timescales—provided that the DM is accurately known.

Software for understanding the pulsar population

When we consider the pulsar population as a whole, we can learn interesting things about their birthrate, kinematics and evolution. The best way to do this is to perform Monte Carlo simulations of the Galactic population of pulsars. By modeling the major pulsar surveys it is possible to tweak the parameters of the input population until it mirrors what we have discovered. There are at least a half a dozen different groups that have attempted such studies, but none of the codes are publicly available.

These studies often vary in their approach and complexity. The most complicated generate each pulsar from birth and follow the trajectory through the Galaxy by modeling the Galactic potential. Simpler models just assume that, by the time a pulsar dies, the effect of acceleration in the Galactic potential is small and ignore it. The right approach depends on the issue you wish to address. Millisecond pulsars live for many oscillations in the Galactic potential whereas magnetars spin down very rapidly. Short-cuts invoked to save computer time a decade ago are becoming less important as computers grow in processing power.

A modern approach might be to model the Galactic potential and generate pulsars every N years with some initial Galactocentric and Z distribution with a variable velocity distribution. By defining an initial period and magnetic field distribution it is easy to determine the period and magnetic field distribution of the population at any instant in time. By assigning a luminosity law as a function of period and magnetic field strength, it becomes possible to determine the radio flux density of a given pulsar at the position of the Sun. A model of the distribution of free electrons and scattering can then determine the dispersion measure and scattering of the pulsar and its detectability in various surveys can then be determined by comparison with a formula such as

$$S_{\min} = \frac{10(T_{\rm rec} + T_{\rm sky})}{G(BN_{\rm p}t)^{1/2}} \left(\frac{P}{P-w}\right)^{1/2}$$

where $S_{\min}$ is the minimum detectable flux density, $T_{\rm rec}$ and $T_{\rm sky}$ are the temperatures in kelvin of the receiver and sky respectively, G is the antenna gain in K Jy^{-1}, B the bandwidth in hertz, $N_{\rm p}$ is the number of polarizations of light (maximum 2), t the integration time, P the period of the pulsar and w the observed width of the pulsar, a combination of the intrinsic width, scattering, DM smearing and the sampling time of the data. If the width is larger than one pulse period the pulsar is invisible in a standard pulsar search.

Although such codes are popular, in my opinion they often tell us more about what we do not know or cannot really say about the pulsar population than what we do know about it. Any estimate of the pulsar birthrate should not be trusted to better than a factor of 2. Anyone who has taken part in a pulsar survey will tell you that (especially in recent times) the effects of interference on a survey's sensitivity are impossible to accurately estimate.

Software: Stellar Photometry

The term 'photometry' refers to the accurate determination of the apparent brightness of an astronomical object. Differences in brightness as measured through several colored-glass or interference FILTERS (for example) permit the definition of color indices, from which the temperature, chemical composition or other properties of the object can be approximately inferred. Changes in the apparent brightness of certain types of astronomical object over time also allow interesting conclusions to be drawn about their intrinsic nature. Photometry plays a key role in the measurement of the ages of star clusters and the distances of external galaxies.

Until roughly 1980, nearly all astronomical photometry was done by means of analog measurements of photographic plates (for instance, with an optomechanical device called an 'iris photometer'), or by analog or digital (photon-counting) techniques with photomultipliers. These photometers produced brightness readings which were typically displayed on dials, plotted on strip charts or printed on strips of paper, and it was often quite practical to analyse these raw data with pencil, paper and a slide rule or table of logarithms. However, during the late 1970s electronic area detectors for astronomy became more advanced: first, for a brief period, television-type cameras were employed, but these were soon supplanted by CHARGE-COUPLED DEVICES (CCDs), which remain overwhelmingly the detector of choice to the present day. CAMERAS employing these devices can produce vast quantities of data directly in electronic form, and the only realistic way to convert these bit strings into human knowledge is by computerized data analysis.

There are two properties of the older types of photometric measurement that distinguish them from modern CCD photometry: previously, (1) one observation produced a measurement consisting of one number and (2) the astronomer attempted, at the time of the observation, to measure *only* the particular object of interest, isolating its light from that of other, nearby astronomical objects. Two or more astronomical objects which lie too close together on the sky cannot be effectively measured either with a photoelectric photometer, owing to the large measuring aperture needed (see below), or on a photographic plate, owing to its nonlinear response to the incoming light. In a modern area detector, which automatically produces a linear brightness map of a given patch of sky, the image of any given astronomical object will usually be spread over several picture elements ('pixels') in the data array, and its brightness will therefore be divided among several simultaneous but separate measurements. Furthermore, the linearity of the detector combined with the fact that each object's image is divided among several pixels allows the *ex post facto* disentangling of the individual brightnesses of numerous different astronomical objects whose images were recorded in the original observation.

There is also one extremely important fact that distinguishes modern photometry of *stars*, in particular, from photometry of other astronomical objects such as galaxies and gaseous nebulae: the apparent angular sizes of all stars as viewed from the Earth (except, of course, the Sun) are very much smaller than the angular resolution permitted by the terrestrial atmosphere and the optical elements of the telescope. Because in any given observation the atmosphere and telescope affect all stars comparably, the perceived images of all stars in a data frame have almost exactly the same shape. (In fact, some camera systems and some techniques—such as observing with ADAPTIVE OPTICS—can produce stellar images whose shape does vary somewhat with position within the frame. Except in the worst cases these variations are small and easily accounted for.) As will be seen below, this property is routinely exploited by modern software to extract stellar photometry from digital images.

The entire process of STELLAR PHOTOMETRY can be broken down into three stages which, for want of better terms, can be identified as follows.

1. *Preprocessing*. The raw digital frames from the telescope are rectified onto a linear intensity scale by operations such as bias subtraction and flat fielding.
2 *Processing*. Each rectified digital frame is searched for the images of individual stars, whose positions and relative brightnesses on an instrumental scale are then determined with the highest possible precision.
3. *Postprocessing*. The results of stage 2 from numerous different frames are combined and calibrated to fundamental magnitude scales by comparison with similar observations of other stars having known brightnesses. Measurements made with different filters can then be compared to form observational colors and/or observations made at different times can be assembled into light curves for variable stars.

The preprocessing stage will not be discussed here. Stage 2 is by far the subtlest part of the whole process, and a great deal of creativity has gone into the development of specialized software for extracting the desired quatities; a few specific software packages for this purpose have become quite widely used (see SOFTWARE IN ASTRONOMY). The postprocessing that occurs in step 3 is conceptually the same as the calibration process for photoelectric photometry. For the most part, general statistical modules or home-grown software have been used for this purpose, so postprocessing will not be discussed in detail here.

The simplest way to extract a brightness measurement for a star which is well isolated from other astronomical objects in its digital data frame simulates the type of measurement that is made with photomultipliers. This older type of photometer contains within it a flat piece of metal with a small hole, or 'aperture', drilled through it, whose diameter generally corresponds to 10 arcsec or more projected onto the sky. The telescope is used to focus an image of a star onto this aperture, which permits the light of the star and some light from the foreground

night-time sky to pass through and be measured by the photomultiplier. With the same aperture, a separate measurement is made for an empty patch of sky with *no* star visible in it, permitting the brightness of the night-time sky alone to be determined. When subtracted from the other measurement, this yields an estimate of the brightness of the star alone. An analogous process may be carried out with stellar images in a digital data frame: one simply defines a synthetic 'aperture' consisting of all the pixels lying within a certain distance from the center of the star image in question, and sums the brightnesses measured in all of those pixels. One also determines the average brightness of the night-time sky from the values measured in nearby pixels which do *not* lie within the images of perceptible stars in the frame. The average sky brightness per pixel is scaled up to the area of the synthetic star aperture and is subtracted from the stellar measurement. This difference represents the brightness measurement for the star alone.

The size of the best digital 'aperture' to use in synthetic-aperture photometry depends on several factors. To provide a reliable measurement, the aperture must be large enough that a constant *fraction* of the light of any given star will be measured, regardless of where the star falls with respect to the pixel grid of the detector. On the other hand, a large aperture produces a measurement with more observational uncertainty, resulting from the readout noise of the detector, random noise in the contaminating light of the night-time sky, the increased possibility of including other astronomical objects in the 'aperture' and the greater likelihood of encountering a detector blemish or cosmic-ray event in the data. For comparing brightnesses of different stars measured in the *same* data frame, a fairly small aperture (perhaps of order 1 arcsec in diameter) can usually be used, since to the extent that all stellar profiles have the same shape, a fairly small aperture can include a constant fraction of the profile, thus allowing precise *relative* brightness determinations. When it is necessary to compare brightnesses among different frames, however, it is usually necessary to employ a comparatively large aperture (at least several arcseconds in diameter), because differences in SEEING and telescope guiding will cause star images in different frames to have different profile shapes: one must then use a synthetic aperture that is large enough to contain all of the profile variations produced by these causes. In other words, measurements through small apertures have high precision (i.e. the random measuring noise is low) but poor accuracy (i.e. there may be large systematic differences from one data frame to the next due to differences in the stellar profile), whereas large-aperture measurements have low precision but high accuracy (they are noisy, but they mean the same thing from one frame to another).

In cases where numerous stars are measured in a given data frame, it is possible to combine measurements through both small and large apertures to yield results with the desirable properties of both. One can measure all the stars in the frame through a small aperture of fixed size, and one can then remeasure selected bright, well-isolated stars through a larger aperture, also of fixed size. By comparing these two results for the stars that were measured twice, one can derive an accurate mean value for the *ratio* of brightnesses as measured through the two apertures for that frame. A constant brightness ratio corresponds to a constant magnitude *difference*. This difference can then be added to the small-aperture magnitude measurements for faint and crowded stars, to yield the magnitude that *would have been measured* for them through the larger aperture, had it been practical to do so. These magnitudes have nearly as high a precision as the small-aperture measurements (because the correction, if determined from the average of many stars, can have comparatively little uncertainty) and the accuracy of the large-aperture measurements. The actual *or* inferred large-aperture magnitudes for stars in any one frame can then be compared with similarly derived large-aperture magnitudes for stars measured in other frames, even though the image profiles may have been rather different.

In general, while measurements through small apertures contain the least possible noise, the comparatively large corrections required to calculate the corresponding large-aperture magnitudes still do have some uncertainty. If a star is very faint, it is best measured through a very small aperture because in such a case the uncertainty associated with the aperture measurement is more critical than the uncertainty of the correction to the larger aperture (see also DETECTION OF FAINT OBJECTS). Conversely, if the star is bright it is better measured through a large aperture because otherwise the uncertainty of the correction would dominate over the uncertainty of the aperture magnitude. A more elaborate scheme of measurement through apertures of many different sizes can be undertaken, which would allow one to choose for each star the 'best' aperture which offers the optimum combination of uncertainty in the aperture magnitude and uncertainty in the correction. The way in which the instrumental magnitudes measured in a given data frame vary with the radius of the synthetic aperture used is called that frame's 'growth curve' (not to be confused with the spectroscopic 'curve of growth').

Even more precise measurements can be made at the expense of much more computational work by using the technique of 'profile-fitting' photometry. In this method, one exploits the fact that any given star image is spread over several pixels, and the internal shape of the image, broadened by the atmospheric seeing and the telescope optics, can be mapped out. To exploit this approach, one must generate a numerical model of the actual profile shape for star images in each data frame. This model profile is determined from the brightest, best-isolated star images in the frame and must be encoded in such a way that the computer can then predict the actual local brightness that should be measured at any point within the profile of a given star image. This profile, or 'point-spread function' (PSF) as it is called (since it describes the way the image of a point source—a star—is spread

Copyright © Nature Publishing Group 2001

Dirac House, Temple Back, Bristol, BS1 6BE, UK

out by the atmosphere and optics) can be encoded as a simple mathematical formula with parameters describing the variation of the local brightness in the profile as a function of position relative to the center of the star or as a table of actual numerical values extracted from the original data frame, from which specific brightness values are subsequently estimated by interpolation techniques.

An analytic model profile has the advantage of simplicity and computational speed but is limited in its ability to represent complex profiles produced by aberrated optics or guiding errors. A PSF encoded as an empirical look-up table can represent any arbitrary profile shape but is subject to the difficulty of achieving accurate interpolations for stars that fall differently on the underlying pixel grid. Interpolation errors are especially critical when the diameter of a stellar image is less than a few pixels. Again, there are advantages to be achieved by combining the two types of encoding. An analytic function fitted by least-squares techniques to the profiles of several bright, isolated stars in a data frame is generally found to represent the actual form of those profiles with 95–98% fidelity. The numerical differences between the actual observed profiles and the fitted analytic models can then be computed and stored as a look-up table. In using this hybrid PSF to predict the brightness value for a pixel located somewhere in the profile of an arbitrary target star, first a value corresponding to that pixel's location is calculated from the analytic approximation to the PSF, and then a correction to the actual empirical profile is estimated from the look-up table. The analytic approximation to the PSF is simply a mathematical formula, so its contribution to the total profile can be interpolated with arbitrary precision, while the amplitudes of the profile corrections stored in the look-up table represent only of order 2–5% of the total amplitude of the PSF, so that errors in the tabular interpolations are proportionately reduced.

Once the PSF for a given data frame has been defined in suitable computer-accessible form, it can be fitted to the images of all detected stars in that frame using nonlinear fitting techniques. For each star, four fundamental parameters must be determined: the position, in x and y, of the centroid of the star within the frame, the local diffuse sky brightness in the frame (which may vary from position to position because of underlying light from other astronomical objects, such as unresolved stars or nebulosity) and the amplitude of that star's profile above the local diffuse sky brightness. This amplitude is linearly related to the relative brightness of the star, and brightness ratios between stars are readily converted to magnitude differences. Separate positions and magnitudes can be estimated even for stars that are so close together that their images are somewhat blended together in the data frame, by suitable simultaneous fits of overlapping model profiles.

The scaling of the model PSF to match the amplitudes of stellar profiles provides a very precise measure of the relative brightnesses among stars in any given data frame. However, since each data frame has its own PSF that may be quite different in form from those found in other frames, profile-fitting photometry does not necessarily guarantee accurate comparisons from one exposure to another. As a safeguard against the possibility of systematic errors in frame-to-frame comparisons, it is common to compare the relative, profile-fitting magnitudes for a number of comparatively bright, isolated stars in each frame with large-aperture magnitudes for the same stars which have been either measured directly or inferred from smaller-aperture magnitudes with growth-curve corrections. The average difference between aperture magnitudes and profile-fitting magnitudes measured for these stars can be added to the profile-fitting magnitudes for all stars in the frame, resulting in a magnitude scale that is both highly precise and fundamentally accurate.

Bibliography

The rationale behind and statistical properties of synthetic-aperture photometry and magnitude growth curves are discussed extensively in these two papers:

SOHO (Solar and Heliospheric Observatory)

The Solar and Heliospheric Observatory (SOHO) is a project of international cooperation between ESA (the EUROPEAN SPACE AGENCY) and NASA to study the Sun, from its deep core to the outer corona, and the solar wind. SOHO was launched on 2 December 1995, on top of an Atlas/Centaur combination, from Cape Canaveral Air-Force Base in Florida. It reached its operating orbit around the L1 Sun–Earth Lagrangian point in mid-February 1996. For more than two years this unique vantage position has allowed nearly uninterrupted observations of the Sun, 24 hours a day, 365 days a year.

The main scientific objectives of the SOHO mission are

- to study the SOLAR INTERIOR, using the techniques of HELIOSEISMOLOGY,
- to study the heating mechanisms of the solar CORONA through data obtained by imaging telescopes and spectrometers, and
- to investigate the SOLAR WIND and its acceleration processes, again by remote sensing, and by *in situ* particle measurements.

To achieve these objectives SOHO carries onboard a complement of 12 state-of-the-art instruments, developed and furnished by 12 international Principal Investigator (PI) consortia involving 39 institutes from 15 countries. Nine of these consortia are led by European PIs, and the three others by US PIs.

During the nominal mission, from 1 May 1996 to 30 April 1998, the SOHO spacecraft operated extremely well, exceeding its specifications in many instances, while the SOHO instruments collected a large number of data, allowing SOHO scientists to make substantial progress in all three science objectives. Scientific highlights from the nominal mission will be presented below. Because of SOHO's scientific success, ESA and NASA have both committed themselves to a mission extension of several years. On 24 June 1998, during routine maintenance operations, ground controllers lost contact with the spacecraft. Efforts to re-establish nominal communication succeeded seven anguish-filled weeks later, and a team of engineers from ESA and Matra-Marconi, the spacecraft contractor, succeeded in returning the spacecraft to full nominal status. All experiments onboard have been restored to the same operational status as before the accident, despite the extremes in heat and cold endured. In the aftermath of these events the third and last gyroscope onboard the spacecraft failed, but after some initial difficulties ground controllers succeeded in operating SOHO in a gyro-less mode, with the function of the gyros taken over by the reaction wheels.

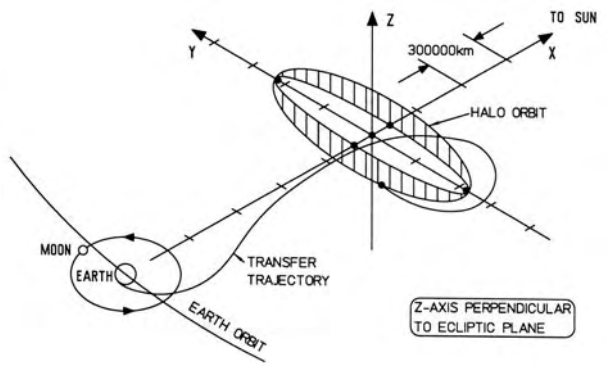

Figure 1. The SOHO orbit around the first Lagrangian point, 1.6 million km sunward from the Earth.

Development and launch

SOHO was first proposed in November 1982, in response to a call for mission proposals by ESA, as a high-resolution spectroscopic investigation of the upper solar atmosphere. In 1983 helioseismology was included as one of the science objectives. After a joint study by European and US scientists, the Science Program Committee of ESA approved SOHO as part of the Solar Terrestrial Science Program (STSP), to be implemented in collaboration with NASA.

ESA and NASA agreed that ESA would take the responsibility for developing the spacecraft, and NASA for the SOHO launch and operations. The 12 SOHO experiments were selected in 1988 after a combined ESA–NASA announcement of opportunity. The SOHO spacecraft was build by a consortium of European industries, led by Matra-Marconi.

SOHO is large, $4.3 \times 2.7 \times 3.7$ m^3, and weighs 1861 kg, with 655 kg for the payload and 250 kg of propellants. The maximum power supply from the solar cells is 1400 W, with a maximum payload consumption of 625 W. SOHO's reaction wheels are designed to provide short-term pointing stability better than 1 arcsec over 15 min, while the roll angle around the Sun is stabilized with the use of a star sensor unit to under 1.5 arcmin over 15 min. Two Gbits of solid state memory, backed up by a one Gbit tape recorder, can store the continuous scientific data rate of 40 kbit s^{-1}, plus 1.3 kbit s^{-1}, for more than 13 h. During continuous contact with the stations of NASA's Deep Space Network (DSN), another 160 kbit s^{-1} of MDI high-rate data are downlinked.

SOHO was launched on top of a Centaur-Atlas combination on 2 December 1995 at 8:08 UT. After one orbit around the Earth the Centaur engine was reignited to set SOHO on course towards the first Lagrangian point, about 1 million miles sunward from the Earth. The launch was so accurate, and the orbital maneuvers so efficient, that SOHO reached its halo orbit six weeks ahead of schedule, on 14 February 1996, with sufficient fuel left to maintain the (unstable) halo orbit for more than a decade, at least twice the time foreseen prior to launch.

Dirac House, Temple Back, Bristol, BS1 6BE, UK

The first four months of SOHO operations were devoted to commissioning and performance verification of the spacecraft and the scientific instruments. By the end of this period the spacecraft was shown to be in excellent shape, with a pointing accuracy of 3 arcmin, better by a factor of 2 than the specification, and a short-term (15 min) stability of 0.3 arcsec, exceeding the specification by a factor of 3. With some minor exceptions, the experiments were all found to operate nominally or better than anticipated.

Experiments and science investigations

An overview of the twelve science experiments onboard SOHO is presented in table 1. The experiments are grouped according to their science objectives. The three interior and surface experiments (GOLF, VIRGO and MDI) use the techniques of helioseismology to measure the properties of the solar interior. GOLF measures the net velocity fluctuations of the entire Sun, VIRGO the intensity variations of the Sun in a dozen zones, and MDI makes maps of the entire surface in velocity, intensity and magnetic field on a 1024 × 1024 CCD. The GOLF and VIRGO instruments are designed to achieve high absolute precision in order to detect the Sun's internal gravity waves (g-modes). MDI is geared towards higher order acoustic modes (p-modes), in order to probe the detailed structure of the SOLAR INTERIOR CONVECTION ZONE. MDI surface maps also allow us to follow the generation and evolution of magnetic fields on a GRANULATION to global scale, with a spatial and temporal resolution sufficient to follow the life-cycle of individual magnetic structures. The continuity of SOHO observations is essential for achieving SOHO's helioseismology objectives. To obtain a signal-to-noise ratio necessary to detect the low-amplitude g-modes, and to measure the frequency of the p-modes with the desired accuracy of a few tens of nanohertz, years of virtually uninterrupted data are required.

SOHO's remote sensing experiments study the outer atmosphere and solar wind. Three of those, SUMER, CDS and EIT, concentrate on the transition region and corona at moderate to high spatial and spectral resolution. The others, UVCS, LASCO and SWAN, avoid the disk to provide data on the outer corona, including the SOLAR WIND ACCELERATION region. The CELIAS solar extreme-ultraviolet monitor (SEM) is a very stable photodiode spectrometer that measures the full disk solar flux in He II at 304 Å, as well as the absolute integral flux between 170 and 700 Å.

SUMER is a UV telescope with a normal incidence spectrometer with high spatial and temporal resolution (∼10 s). It measures line profiles and intensities of UV lines in the range from 500 to 1600 Å, with a resolution of 18 800 to 40 000. Thus SUMER can measure velocities down to 1 km s^{-1}. CDS operates at shorter wavelengths (150 to 800 Å), and consists of a Walter II telescope equipped with both a normal and a grazing incidence spectrometer. It determines line intensities in selected EUV lines to study the temperature and density of coronal structures. EIT obtains full-Sun high-resolution images, limited only by the 2.6 arcsec pixel size, in four emission lines, and corresponding to temperatures of 80 000, 1.3, 1.6 and 2.0 $\times 10^6$ K. EIT's observations provide the morphological context for the spectrographic data from CDS and SUMER.

LASCO is a triple coronagraph with nested concentric, and increasing annular fields of view. It also has a Fabry–Pérot interferometer for spectroscopic measurements with a spectral resolution of about 700 mÅ, in Fe XIV and X, Ca XV, Na D_2 and Hα. UVCS is an occulted telescope equipped with high-resolution spectrometers for spectroscopic observations of the solar corona out to 10 solar radii to determine the source regions, the acceleration and the heating of the solar wind. One UVCS grating is optimized for line profile measurements of Lyα, another for line measurements in the range from 944 to 1070 Å. SWAN, finally, maps the intensity of interplanetary Lyα, with two identical periscope systems, each of which observes one hemisphere at a resolution of 1 arcmin. Its goal is to determine the latitude distribution of the solar wind flux, and its variation. In addition it can measure the shape of the Lyα line at a resolution of about 3×10^5.

Of the three *in situ* particle experiments onboard SOHO, CELIAS studies the solar wind at L1, pristine in comparison with the data affected by the Earth's foreshock, which are collected by near-Earth spacecraft. The CELIAS proton monitor measures ions in the range 0.3 to 6 keV/e, and generates values of the solar wind proton bulk speed, density and north/south flow direction with a 30 s temporal resolution. The CELIAS mass determining time-of-flight (MTOF) sensor is a high-resolution mass spectrometer, which measures the solar wind's elemental and isotopic composition. CELIAS/CTOF, the charge determining time-of-flight sensor has obtained high time resolution charge state spectra for solar wind iron ions, but is no longer fully operational. Finally, CELIAS' suprathermal time-of-flight sensor (STOF) measures ionic charge states of particles with suprathermal energies from just above the solar wind up to low-energy solar flare particles (20–4000 keV amu^{-1}; see SOLAR FLARE OBSERVATIONS), thus bridging the gap between the solar wind instruments and the high-energy particle instruments ERNE and COSTEP.

ERNE and COSTEP are designed to detect Earthward traveling energetic particles ejected from the Sun in the course of flares and coronal mass ejections (CMEs; see SOLAR CORONAL MASS EJECTION: OBSERVATIONS). Electrons are recorded at energies from 44 keV to 50 MeV, and protons from 44 keV to over 100 MeV. Alpha particles are observed from a few MeV/nucleon to over 100 MeV/nucleon. Heavier elements, up to iron, can be identified up to 500 MeV/nucleon.

Operations and data archive

In nominal science operations each SOHO experiment carries out an individual synoptic or baseline science program, complemented for the remote sensing experiments and MDI by a coordinated mode, involving frequent joint

Table 1. An overview of the twelve science experiments on SOHO.

Experiment	Investigation	Technique	Bit rate (kb s^{-1})
Helioseismology			
GOLF (Global Oscillations at Low Frequency)	Global Sun velocity and magnetic field oscillations, harmonic degree $l = 0$–4	Na vapor resonant scattering cell, Doppler shift and circular polarization	0.160
VIRGO (Variability of Solar Irradiance and Gravity Oscillations)	Low degree ($l = 0$–7) irradiance oscillations and solar constant	Global Sun and low-resolution (12 pixels) photometers, active cavity radiometers	0.1
SOI/MDI (Solar Oscillations Investigation/ Michelson Doppler Imager)	Velocity oscillations with harmonic degree up to 4500	Doppler shift with Fourier tachometer, 4 and 1.5″ resolution	5 and 160
Solar atmosphere remote sensing			
SUMER (Solar Ultraviolet Measurements of Emitted Radiation)	Plasma flow characteristics (temperature, density, velocity) chromosphere through corona	Normal incidence spectrometer, 50–160 nm, spectral resolution 20 000–40 000, angular res. 1.2–1.5″	10.7 or 21
CDS (Coronal Diagnostic Spectrometer)	Temperatures and density: transition region and corona	Normal and grazing incidence spectrometers, 17–80 nm, spectr. res. 1000–10 000, angular res. 2″	11.5 or 23
EIT (Extreme-Ultraviolet Imaging Telescope)	Evolution of chromospheric and coronal structures	Full disk images (42′ × 42′ with 1024 × 1024 pixels) in He I, Fe IX, Fe XII and Fe XV	2.0 or 6.6 or 27
UVCS (Ultraviolet Coronagraph Spectrometer)	Electron and ion temperature densities, velocities in corona (1.3–10$R_\odot$)	Profiles and/or intensity of spectral EUV lines (Lyα, O VI, etc)	5
LASCO (Large Angle and Spectrometric Coronagraph)	Coronal evolution, mass, momentum, and energy transport (1.1–30 $R_\odot$)	One internal and two externally occulted coronagraphs, Spectrometer for 1.1–3$R_\odot$	5.9 or 9.2 or 27
SWAN (Solar Wind Anisotropies Study)	Solar wind mass flux anisotropies and temporal variations	Scanning telescopes with hydrogen absorption cell for Lyα light	0.2
Solar wind 'in situ'			
CELIAS (Charge, Element, and Isotope Analysis System)	Energy distribution and mass, charge and charge state of ions 0.1–1000 keV/e	Electrostatic deflection, time-of-flight measurements, and solid state detectors	1.5
COSTEP (Comprehensive Suprathermal and Energetic Particle Analyser)	Energy spectrum of protons, α-particles, and electrons, composition of ions	Solid state detectors and electrostatic analysers	0.3
ERNE (Energetic and Relativistic Nuclei and Electron experiment)	Energy distribution and composition of ions (p, Ni), 1.4–540 MeV/n, and electrons 1–25 MeV	Solid state, and plastic and crystal scintillator detectors	0.71

operations programs (JOPs), occasional targets of opportunity, and regular campaigns with other spacecraft and ground-based observatories (GBOs).

The SOHO experiments were designed to complement each other, and through intense and innovative use of the Internet, SOHO has lifted the standard, frequency and documentation of coordinated solar observations to a new level. Images, observing sequences and target coordinates are exchanged instantaneously, while the data are automatically linked through the SOHO catalogs. Hundreds of campaigns have been carried out during the nominal mission. These vary from large-scale campaigns of several hours daily for one or two weeks, involving GBOs all over the world as well as other spacecraft (YOHKOH, TRACE, ULYSSES), to instrument intercalibrations of an hour or two, occasionally supported by rocket underflights.

The center of SOHO operations is the Experiment Operations Facility (EOF) at NASA's GODDARD SPACE FLIGHT CENTER, where experiment commanding, real-time coordination and long-term planning are executed. Representatives of the six interactive experiments (SUMER, CDS, EIT, MDI, UVCS and LASCO) are permanently present at the EOF to operate the mission in collaboration with the NASA Flight Operations Team and the ESA/NASA Project Sci-

entist Team. The science observing programs are planned through a regular, nested series of meetings, that lead to a schedule that is both predictable enough to prevent overburdening operations scientists, and flexible enough to allow rapid reaction to observing opportunities.

SOHO is unique among solar physics missions in that data are received 'live', and the experiments commanded in near real time directly from the EOF for about 8 h a day. Scientists, from behind their workstations, can retarget and reprogram their experiments in a matter of minutes in response to events on the Sun.

Four SOHO data archives are being constructed, one in the US, at Goddard Space Flight Center, and three in Europe, at Medoc in Orsay, RUTHERFORD–APPLETON LABORATORY in the UK, and in Torino. These archives contain all experimental data, except for the MDI helioseismology data, which are stored in a separate facility at Stanford. To make the data easily accessible through the Internet for the widest possible group of scientific users, and to facilitate multi-experiment data analysis, the SOHO archive has a uniform data format (FITS), uniform access to all experimental data, a campaign catalog that cross-links experimental data of coordinated observations, a collection of synoptic data from observatories world wide, and a complete set of analysis software. The main SOHO catalog, an event catalog and the experiment catalogs round out the archive.

Science highlights

Exploitation of the enormous number of data from the SOHO nominal mission is only in its initial phase, but already a large number of exciting new results have been announced. A brief synopsis is given below.

Solar surface and interior

MDI medium angular degree data have provided the most precise measurements of the sound speed profile and the differential rotation profile within the Sun, thus setting new boundaries for the solar model

Application of a new technique, called time–distance helioseismology, to high-resolution MDI data has provided the first images of the convection zone of a star; maps of vertical and horizontal flow velocities, as well as sound speed variations in the convection zone, just below the visible surface.

MDI data have revealed a jet-like flow near the poles, which is totally inside the Sun and cannot be seen at the surface. Circling the Sun at about 75 deg latitude, this flow consists of a flattened oval region about 30 000 km across where material moves about 10% faster than its surroundings.

MDI data have also revealed at least six differentially rotating belts, three in each hemisphere. These belts are more than 65 000 km across and they move about 15 km h^{-1} faster than their surroundings.

The use of the new time–distance helioseismology technique in analysing MDI data has yielded that the entire outer layer of the Sun, to a depth of at least 25 000 km, is slowly but steadily flowing from the equator to the poles at about 80 km h^{-1}, fast enough to transport an object from the equator to the pole in just over a year.

High-precision MDI measurements of the Sun's shape and brightness obtained during two special 360° roll maneuvers of SOHO have produced the most precise determination of solar oblateness ever. There is no excess oblateness. These measurements unambiguously rule out the possibility of a rapidly rotating core and any significant solar cycle variation in the oblateness.

Results from the radiometers and photometers of VIRGO confirm that active regions modulate total and spectral irradiance on time scales of days to weeks.

Solar corona and solar wind

The UVCS coronagraph has revealed dramatic differences in the line widths of the strong hydrogen Lyα line and even more so in the resonance lines of O VI in coronal streamers and CORONAL HOLES at heliocentric heights from 1.25 out to 3.5 solar radii. Preferential acceleration of high mass ions affords one possible explanation for generating the observed velocities in the O VI ions.

Combined Doppler-dimming measurements of UVCS, LASCO white-light images of the solar corona, and radio scintillation measurements by the Galileo spacecraft have yielded new insight into the origins of the slow and fast solar wind. While the prevailing view is that the fast solar wind originates only in polar coronal holes and their equatorial extensions, the new measurements are interpreted as evidence that the slow solar wind is limited to the axes (or 'stalks') of coronal streamers while the fast solar wind dominates the corona.

A UVCS spectroscopic study of the composition in coronal streamers has revealed an ionization temperature of 1.6×10^6 K. The elemental abundances in the leg of the streamers and in ACTIVE REGION streamers are similar to those observed in the slow solar wind, indicating that the slow solar wind originates at the legs of the coronal streamers.

The CDS and SUMER spectrometers have observed extensive evidence of explosive events in transition-region lines. These could be the signature of MAGNETIC RECONNECTION events in nearby small magnetic dipoles, observed in MDI magnetograms. These events seem to account for a substantial part of the energy that is needed to heat the corona.

Coordinated measurements by SUMER and CDS have provided new observations of the temperature structure of coronal holes. The temperature measured at the base has a higher value than anticipated, of the same order as that of closed field regions (about 10^6 K), but it decreases much more rapidly with height than had been expected, falling to about 0.3×10^6 K at 1.3 solar radii. This is not consistent with a thermally driven fast solar wind.

Time-lapse sequences of white-light images from the LASCO coronagraph, obtained during sunspot minimum conditions in 1996, have been used to measure, for the first time, the acceleration of the solar wind. The outflow

of about 150 features in the streamer belt has been tracked between 3 and 30 solar radii. The speed versus radial distance profiles cluster around a parabolic path characterized by a constant acceleration of about 4 m^{-2} throughout the field of view. That profile is consistent with an isothermal solar wind expansion at a temperature of $\approx 1.1 \times 10^6$ K and a sonic point around 5 solar radii.

EIT and LASCO have recorded the very onset and evolution of several Earth-directed CMEs, a few of which actually hit the Earth's magnetosphere (see MAGNETOSPHERE OF EARTH). This type of observation holds considerable promise for the further development of space weather forecasting methods. The LASCO instrument is collecting an extensive database for establishing firm statistics on CMEs and their geomagnetic effects.

The LASCO coronagraphs have discovered more than 50 sungrazing comets, several of which were observed crashing into the Sun (see COMETS: KREUTZ SUNGRAZING).

The *in situ* particle detectors (ERNE and COSTEP) regularly detect high-energy protons, electrons and alpha-particles, in the aftermath of prominence eruptions and CMEs, while CELIAS, SOHO's solar wind analyser, has doubled the number of elements and isotopes previously recorded in the solar wind. During a Venus disk passage CELIAS also observed, for the first time from such a large distance, pick-up ions from the Venusian ionosphere, finding a much smaller diffusion cone than anticipated.

SWAN, looking away from the Sun, has recorded full-sky Lyα maps at a resolution and signal-to-noise ratio of at least a factor 10 better than previous observations. From these maps, the latitude distribution of the solar wind is determined.

Solar Abundances

What is the Sun made of? This fundamental question only received an answer about 70 years ago. H N RUSSELL, whose name is associated with much pioneering research in astrophysics during the first half of this century as well as with a series of basic work in atomic spectroscopy, made the first quantitative analysis of the chemical composition of the SOLAR PHOTOSPHERE in 1929. Using eye estimates of solar line intensities, he succeeded in deriving the abundances of 56 elements. He also showed that the Sun and, finally, the universe were essentially made of hydrogen; this observation took some time to be accepted by the whole astronomical community. Many of the remarkable features correlated with nuclear properties (see figure 1), giving clues to the origin of the different elements, were already present in Russell's results.

Is the solar composition unique or does it vary with time and/or from one solar layer to another? The only obvious expected variation is in the central layers, where, because of thermonuclear reactions, the hydrogen content decreases, leading to an increase in the helium content (see NUCLEAR REACTION RATES). More subtle and unforeseen variations in the chemical composition have, however, been observed recently. During the solar lifetime, the convective zone reservoir which fills the outer solar layers is slowly enriched in hydrogen from the radiative zone below it, whereas it slowly loses, through its lower boundary layer, about 10% of all the heavier elements (see SOLAR INTERIOR: CONVECTION ZONE). In the outer atmospheric layers, and particularly in the very heterogeneous solar CORONA, the observed composition is variable in different types of solar matter and a fractionation occurs in the low chromospheric layers: elements of low first ionization potential ($\leq$10 eV) show abundances larger than in the photosphere.

In spite of these subtle variations, it is possible to define a standard solar chemical composition, essentially derived from spectroscopic analysis of the solar photosphere.

Interest of solar abundances

The chemical composition of the Sun is obviously a key set of data for modeling the interior as well as the atmosphere of the Sun.

The Sun, being the best-known star, has always been considered as the typical star, the reference to which the abundance analyses of other stars are compared.

The standard abundance distribution as shown in figure 1 is also the basic set of data that have to be reproduced by nucleosynthesis theories; it also plays a key role in modeling the chemical evolution of galaxies and of the universe.

The Sun is also unique because chemical composition data can be measured in other objects of the solar system such as the Earth, Moon, planets, comets, meteorites. These data are very important for modeling the evolution of the solar system (see SOLAR SYSTEM: FORMATION).

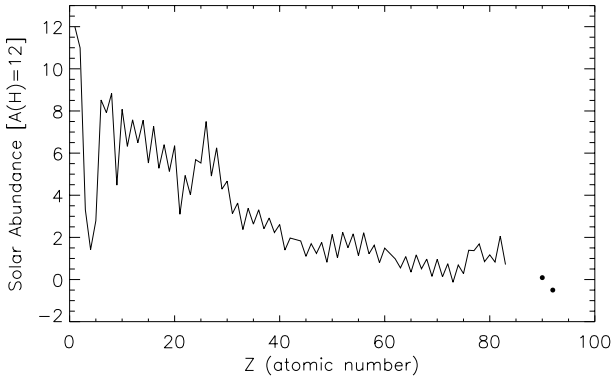

Figure 1. Logarithmic distribution of the abundance of the elements relative to hydrogen as a function of the atomic number, Z.

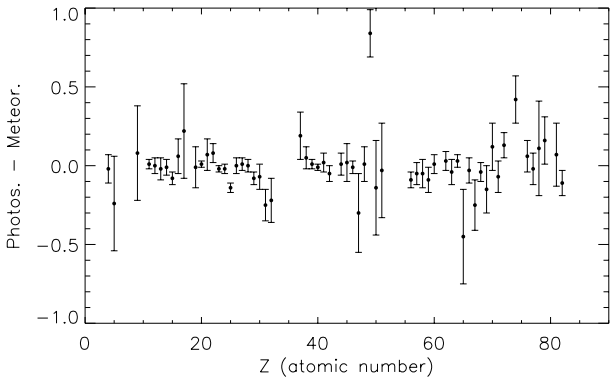

Figure 2. Difference between solar and meteoritic abundances of elements, in the usual logarithmic scale, as a function of Z. Error bars represent the uncertainty of the solar abundance determinations. The point representing Li falls outside of this figure (−2.21).

Sources of solar abundances

Solar abundances can be derived by very different techniques and for very different types of solar matter, from the interior to the outermost coronal layers. Using spectroscopy in a very large wavelength range, we can derive the chemical composition of the photosphere, CHROMOSPHERE and CORONA and also of SUNSPOTS. Particle collection techniques from space allow us to measure the chemical composition of the SOLAR WIND and of SOLAR WIND ENERGETIC PARTICLES, emitted when the Sun is active. We can also obtain information on solar flares from GAMMA-RAY ASTRONOMY. Finally, calibration of theoretical solar models and direct inversion of solar oscillation data allow us to derive the solar abundance of helium. Note also that lunar soils contain a record of the past chemical history of the Sun.

For different reasons and because of the variations in chemical composition, all of these sources of abundance results do not have the same weight. The solar photosphere is actually the layer from which we have

Abundances are given in the logarithmic scale usually adopted by astronomers $A_{\rm el} = \log N_{\rm el}/N_{\rm H} + 12.0$, where $N_{\rm el}$ is the abundance by number. By definition the abundance of hydrogen is exactly $A_{\rm H} = 12.0$.
[a] Values between square brackets are not derived from the photosphere, but from sunspots, solar corona and solar wind particles. Values between parentheses are less accurate results.

the largest number of data. Actually, 65 elements, out of 83 stable elements, are present in the photospheric spectrum; other sources of solar abundances only concern a limited number of elements. The photosphere, just above the convection zone, is a well-mixed region whereas the outer solar layers show a very heterogeneous and changing structure. Furthermore, it is also the layer that was studied quite a long time before the other layers for an obvious reason: the solar photospheric spectrum has been recorded for quite a long time with high resolution and high signal-to-noise ratio. For all these reasons, photospheric abundances are adopted as a reference for all the other solar (and stellar) data.

Solar photospheric abundances

The basic data for deriving photospheric abundances are from the photospheric spectrum. Solar photospheric spectra with very high resolution and very high signal-to-noise ratio, obtained from the ground and from space, are now available for quite a large wavelength range, from the ultraviolet to the far infrared.

The strength of a line in the ABSORPTION SPECTRUM is directly related to the abundance of the element producing the line. The exact relation between these two quantities can be obtained if the physical conditions and physical processes of the layers where the line is formed are known. Empirical modelling of the photosphere has now reached a rather high degree of accuracy. Physical processes are also well known. Actually, in the photosphere, collisional processes dominate, which allows us to simplify the treatment. From the line strength, now measured with high accuracy, or directly from the fit of the predicted and observed spectra, the so-called spectral synthesis technique, it is possible to derive rather accurate values for the product of the abundance of the element producing the line, relative to the hydrogen abundance, times the transition probability of the line (see also SOLAR SPECTROSCOPY AND DIAGNOSTICS). The ratio $N_{\rm el}/N_{\rm H}$ is a natural measurement of abundance because the continuum is essentially produced by the opacity due to hydrogen species whereas the absorption line is the result of an additional opacity caused locally by a given element.

One of the largest sources of uncertainty of solar photospheric abundances comes from the inaccuracies of the transition probabilities. These data really play a key role in solar spectroscopy. Most of the progress in our knowledge of the solar photospheric chemical composition during the last decades has been mainly, if not uniquely, due to the use of more accurate transition probabilities. Actually, we believe that the dispersion of solar photospheric abundance results reflects the internal accuracy of the transition probabilities used to derive the abundances. Also, unfortunately, too few very accurate transition probabilities are available for the atomic and molecular lines present in the photospheric spectrum.

In table 1, we give the latest data for the solar photospheric abundances relative to hydrogen. The values are given in the logarithmic scale usually adopted by astronomers $A_{\rm el} = \log N_{\rm el}/N_{\rm H} + 12.0$, where $N_{\rm el}$ is the abundance by number. It is to be noted that such a scale was originally adopted in order to avoid negative numbers for the least abundant elements. It is still used nowadays even if two values are now negative numbers i.e. their abundance is less than one million millionth that of hydrogen—rather rare!

As may be seen from table 1, the photospheric abundances of a few elements cannot be measured in the photosphere, because these elements do not show lines in the photospheric spectrum, the most important of them being helium. This does not at all mean that these elements are absent in the Sun. Actually, this is purely for basic spectroscopic reasons: under the physical conditions in the photosphere, with a typical temperature around 5000 K, no line of these elements (neutral or once-ionized species) falls within the wavelength range covered by the photospheric spectrum.

Comparison with meteorites

Although most of the matter of the solar system is contained in the Sun, very useful information concerning the chemical composition of the initial solar nebula and its evolution can be obtained from the observations of other bodies of the solar system. Early terrestrial data very rapidly showed that the Earth suffered from heavy chemical fractionation since its formation but results of measurements made on METEORITES, during the first half of this century, soon showed many regularities, as seen in figure 1.

Most meteorites suffer from differentiation due to melting after condensation in the parent body. However, the so-called CI carbonaceous chondrites, has preserved the bulk composition of the stellar nebula from which they condensed, except for the highly volatile elements (H, C, N, O and the rare gases) which partly escaped.

Meteoritic chemical composition can now be measured with very high accuracy. When compared with photospheric results, there were past discrepancies, for several elements, but the discrepancies have gone away as the photospheric values have become more accurate. Now, as seen from figure 2, the agreement between the photosphere and CI chondrites is remarkably good. The uncertainties essentially come from the photospheric results which cannot be obtained to better than 10–20%. The few discrepant points can be accounted for by the larger uncertainty of some photospheric results, especially for elements which only show very few blended lines in the photospheric spectrum.

Table 1 allows us to define a 'standard abundance distribution' (also sometimes called 'cosmic abundance' or 'local galactic abundance') by combining photospheric results, for elements partly lost by meteorites, with meteoritic results for the other elements.

A few special cases

For different reasons that will become clear in the following, a few elements deserve particular comments.

Helium

In 1868, a new element was discovered in the solar spectrum obtained during an eclipse. The name of the Sun was given to this unknown element, namely helium. It was only discovered on Earth in 1895.

Despite its name and its very high abundance, about one-tenth of hydrogen, the most abundant element, He is not present in the photospheric spectrum, for purely spectroscopic reasons, as explained previously, and it is largely absent from the meteorites. Solar wind and solar energetic particles show a very variable and rather low value when compared with values observed in hot stars and in the interstellar medium from H II regions around us. Coronal values derived from spectroscopy still have too large uncertainties, $N_{\rm He}/N_{\rm H} \approx 8 \pm 1.5\%$. Among the giant planets, values are still too uncertain and fractionation might have been at work in some of them.

Progress in our knowledge of the solar helium content has recently come from standard solar models as well as non-standard models and also from the direct inversion of HELIOSEISMIC OBSERVATIONS. The calibration of

Dirac House, Temple Back, Bristol, BS1 6BE, UK

solar theoretical models, i.e. the fit of a theoretical model to the presently observed characteristics of the Sun (age, mass, diameter, luminosity), leads to the abundance of helium in the protosolar cloud from which the Sun formed ($N_{He}/N_H = 9.8 \pm 0.4\%$). Inversion of helioseismic data leads to a very accurate, but smaller, value, $N_{He}/N_H = 8.5 \pm 0.07\%$; this is the present solar abundance of helium in the outer convection zone. The difference between these two values is now explained by slow element diffusion at the base of the convection zone during the solar lifetime, as already mentioned in the introduction.

Astronomers often use the abundances by mass of hydrogen (X), helium (Y) and all the other elements together, the metallicity (Z), in a scale where $X + Y + Z = 1$. The numbers cited above become $Y = 0.275 \pm 0.01$ or $A_{He} = 10.99 \pm 0.02$ in our logarithmic scale, at the birth of the Sun, and $Y = 0.248 \pm 0.02$ or $A_{He} = 10.93 \pm 0.004$, as the present value in the solar outer layers.

Lithium, beryllium, boron

The strikingly low abundances of these light elements are a direct consequence of their low nuclear binding energy; at temperatures of the order of a few million kelvins, these nuclei are destroyed by proton collisions.

In the Sun, meteoritic and photospheric abundances of Be and B agree within the error bars, whereas Li is 160 times less abundant in the (present) photosphere than in the meteorites, i.e. at birth of the Sun. Lithium is the most fragile of these three elements and its solar destruction rate could be explained if the solar convection zone reached a little deeper layers than now deduced from helioseismology. So additional mixing, just below the convection zone, has to be added in order to explain the observed solar lithium depletion.

Carbon, nitrogen, oxygen

These elements which have largely escaped from meteorites are key elements. Because of their large abundances, they are the main contributors to the metallicity (O 47%, C 17%, N 5%) and they are also very important contributors to the opacity which plays a crucial role in modeling the solar interior.

Although coronal measurements of the CNO abundances are certainly very helpful, the solar abundances of these three elements rely heavily on photospheric analyses.

In spite of the fact that the solar photospheric abundances of these elements can be derived from a large number of indicators, atoms as well as diatomic molecules made of C, N, O and H, the uncertainties of the solar results are uncomfortably too large, partly because of the lack of very accurate transition probabilities.

Neon, argon

These two noble gases do not appear in the solar photospheric spectrum, for the reasons already described, and are largely lost by meteorites. It is hoped that values obtained for the outermost solar layers, from coronal spectra, solar wind and solar energetic particle measurements as well as gamma ray spectroscopy of solar flares, do not suffer from the fractionation mentioned in the introduction and can be used as representative of the present solar photosphere.

Isotopic abundances

Because isotopic shifts in atomic lines are extremely small, it is impossible to obtain isotopic ratios for most of the elements. For a few elements, however, such as C, O and Mg, which appear in diatomic molecules, we can derive estimates of the solar isotopic composition, with rather large uncertainties. Isotopic data can be obtained from solar wind measurements for He, Ne and Mg.

Isotopic ratios for all the elements can be measured with high accuracies for terrestrial material. They agree with the results obtained from meteorites although 'isotopic anomalies' are observed which are, however, confined to a very small fraction of the meteorites. Thus the method is to take solar abundances for the elements together with isotopic ratios as derived on earth in order to obtain the solar abundances of individual nuclides.

Conclusions

With the solar chemical composition presented in table 1, the usual mass abundances are $X = 0.735$, $Y = 0.248$ and $Z = 0.017$ with $Z/X = 0.023$.

The solar abundances are in excellent agreement with the meteoritic abundances derived from CI carbonaceous chondrites. The effects of element migration at the bottom of the convection zone are, however, not observed. This is puzzling although not surprising. Actually, the uncertainties of the photospheric abundance results are still too large to allow such a faint effect to be detected.

Solar Active Regions

Solar active regions form where the tops of loops of magnetic flux, shaped like the Greek letter omega (Ω), emerge into the solar atmosphere where they can be seen. These Ω loops are thought to be generated by the solar dynamo, located deep within the Sun (see DYNAMOS: SOLAR AND STELLAR). The appearance of active regions depends greatly on the radiation used to image them, as well as the angle at which they are observed. When seen projected against the dark sky at the edge of the Sun (called the LIMB), the magnetic field of an active region is traced by glowing arches of gas confined within CORONAL LOOPS (figure 1). When projected against the solar disk the appearance of active regions is much different. In hydrogen Hα, at low telescopic resolution, one sees bright SOLAR CHROMOSPHERIC PLAGE (figure 2). At higher resolution, the relatively cool (chromospheric) loops of the active region appear (figure 7). In x-rays, the much hotter (coronal) loops of the active region are seen (figure 3).

All of these active region loops, whatever their temperature, trace out magnetic field lines. Plage appears at their footpoints, where the loops pass through the chromosphere and photosphere. At one footpoint of each loop the magnetic field comes out of the Sun (north polarity), and at the other footpoint it goes back into the Sun (south polarity). Active regions are formed of many such bipolar pairs of footpoints connected by coronal loops, as if a large magnet was buried beneath the visible solar surface at the site where the active region appears.

The high density at which magnetic loops are packed together at their photospheric footpoints is the distinctive feature that makes active regions different from the surrounding *quiet* atmosphere. The effects of the magnetic field on the temperature and density structure of an active region depend on its strength, the relative fraction of the active region it fills (compared with non-magnetic regions) and its topology, i.e. how each point is connected to another. In chromospheric plage—the bright areas that can be seen in figure 2 both scattered around the quiet Sun (two examples shown) and within the active region itself—magnetic loops are packed 10–100 times more densely than in the quiet Sun. In SUNSPOTS, loops are packed so tightly that there is no significant amount of unmagnetized gas, which inhibits the flow of heat by convective motions and makes sunspots cooler and darker than their surroundings. Finally, irregular dark strands of gas called solar FILAMENTS form where the magnetic field lines dip to form valleys in the corona that can hold ionized gas (which cannot easily move across field lines) in clouds above the photosphere. Several such filaments can be seen in figure 2, both inside the active region and outside it, in the quiet solar atmosphere. When filaments are seen in profile at the solar limb, they are called SOLAR PROMINENCES.

Active regions come and go, and their lifetime depends to a large extent on their size. Active regions have no preferred size; they form a continuous distribution, with many more small ones than large ones. The smallest

ones that can be observed depend on telescope resolution, and presumably there are many still smaller ones that have not been resolved. In the photosphere the largest and most long-lived active regions have areas in the range 50–100 000 Mm^2, which is only 1–2% of the surface area of the Sun, but about 100–200 times greater than that of the Earth. The x-ray image shown in figure 3 illustrates the extreme range of sizes seen in the solar corona. The smallest active regions, and also the most short lived, are called ephemeral solar active regions, which are often only a few thousand km across. Several tiny x-ray bright points, which mark the sites of ephemeral solar active regions, can be seen the the northern hemisphere of the image in figure 3 (see SOLAR CORONA: X-RAY BRIGHT POINTS; SOLAR ACTIVE REGIONS: EPHEMERAL). The active regions in which phenomena such as SOLAR FLARES and sunspots occur typically fall in the size range from 10 000 to 100 000 km, and live for a month or two (one or two solar rotations). Many such active regions can be seen in figure 3. It happens that, at the time of this image, more were located in the southern hemisphere than in the northern, but that is not a general rule. At the extreme end of the distribution of sizes and lifetimes are SOLAR ACTIVITY COMPLEXES, which are made up of several active regions. The interconnected active regions at and below the center of the solar image in figure 3 collectively form such a complex of activity.

Active regions have several interesting properties, which vary either on the 22 yr SOLAR CYCLE or the 11 yr sunspot cycle. Very few active regions, or the sunspots they contain, are present at sunspot minimum—sometimes, none at all. In contrast, near sunspot maximum, it is not usual to find five to ten active regions on the hemisphere visible from Earth. Their emergence frequency varies by about a factor of 8, in phase with the sunspot cycle. On the other hand, the shape of the size distribution of regions does not change significantly from minimum to maximum.

The orientation of the magnetic polarity pair in active regions, with respect to the direction of solar rotation (from left to right, solar east to west, if north is up), follows what is called the Hale–Nicholson polarity law during the solar cycle. As can be seen in figure 4 one magnetic polarity tends to predominate at the leading (right) edge of all active regions in one hemisphere, whereas the opposite polarity predominates at the leading edge in the other

hemisphere. The polarity that dominates in a given hemisphere reverses every 11 yr, repeating with the 22 yr period of the solar cycle. Interestingly, the Hale–Nicholson polarity law is only an approximation, and many regions are exceptions. These exceptions are attributed to kinks in Ω loops and buffeting of them by convective motions.

The solar latitude at which active regions emerge varies from about 60° at the start of each sunspot cycle to very close to the equator at its end almost 11 yr later. The regions that emerge at high latitudes early in the solar cycle tend to be very small—not large enough to contain sunspots, which tend not to be seen in regions above 30° or so. As the cycle goes on, the latitude of emergence proceeds toward the equator, and the size of the active regions tend to increase. This tendency for active regions to emerge at progressively lower latitudes as the sunspot cycle progresses is called Spoerer's law. There is also a tendency for the smaller regions to be spread out more in latitude of emergence, which may be attributed to greater buffeting by convection.

The spots on the leading edge of active regions tend to be closer to the equator than those that follow, so the axes of the active regions appear to be tilted with respect to the equator. Several clearly tilted regions appear in figure 4; in the north, white polarity leads and tends to be closer to the equator, and in the south, black polarity plays that role. When enough regions are studied, it becomes clear that this tilt depends on latitude, being only about 1–2° near the equator, but increasing to 5–8° at latitude 25° The flux in the leading part of active regions also tends to be concentrated in fewer larger spots than the following part (see figure 4, lower right quadrant, and figure 5). This

morphology has been ascribed to the dynamics of gases in flux loops as they rise through the convection zone and expand. Gas tends to flow toward the following leg of the Ω loop, increasing its cross-section. This reduces the field strength in the following leg, making it more easily shredded into smaller strands by convection.

The rope-like magnetic field structures of active regions in the northern hemisphere tend to be twisted weakly in a left-handed sense, and those in the southern, right-handed. As a result, coronal loops in the south tend to be shaped like an S, and those in the north, the mirror image of an S. These properties, and some of the other properties described above, are thought to be determined by the forces felt by convection zone flux tubes (see SOLAR INTERIOR: CONVECTION ZONE FLUX TUBES). The fields of active regions are twisted by motions of the rising gas, which tend to rotate in opposite directions in the two hemispheres under the influence of the Coriolis force. As well, they are buffeted by strong turbulence. The same tendencies of tilt and asymmetry seen in active regions appear in emerging magnetic flux tubes (see SOLAR INTERIOR: EMERGING MAGNETIC FLUX TUBES) that have just appeared in the atmosphere after their journey through the convection zone.

Active regions are sites of strong heating of the outermost solar atmosphere (corona). Hence, active regions are much brighter than their surroundings in coronal x-ray images (figure 3). Active regions are filled with coronal loops, which outline magnetic field lines along which the ionized coronal plasma is forced to move. In active regions, magnetic fields are very strong, ranging from roughly 1000 to 3000 G. These fields are about 10 000 times stronger than the 0.3 G field of the Earth at the equator. In a mature active region, the amount of magnetic flux (the product of the strength of the magnetic field and the area it covers) ranges from 10^{19} to 5×10^{22} Mx. These magnetic fields carry currents—as much as 10^{12} A. In comparison, a 100 W light bulb carries a current of about 1 A. Nevertheless, it is not understood just how the vast

amounts of energy contained in these currents is converted into coronal heating, solar flares or coronal mass ejections (see SOLAR CORONAL MASS EJECTION).

Active regions—photosphere to corona

Active regions extend from below photosphere far into the corona. The physical conditions change dramatically over this range. In and below the photosphere, the gas is so dense that its turbulent motions push the magnetic fields around. Such motions serve to break up the magnetic fields into bits and pieces outside active regions, as well as to concentrate magnetid fields in individual dark sunspots and SUNSPOT PORES within them. Active regions are surrounded by brighter granular areas which are almost field free (figure 5). As one goes higher in the solar atmosphere, the density of the gas falls off more rapidly than the strength of the magnetic field. In and above the chromosphere, the magnetic field can no longer be forced to move by the flow of the gas, and it spreads out to fill all space. Hence, the appearance of active regions is much different in the photosphere, where kinetic and thermal terms dominate the energy budget, from in the chromosphere and corona, where the magnetic field is more important.

At some depth below the visible surface convection zone flux ropes are shredded into smaller strands, as envisioned in figure 6. Motions within granules, supergranules and perhaps even larger structures (see SOLAR PHOTOSPHERE: GRANULATION; SUPERGRANULATION) push these strands around to form the sunspots and pores of an active region, such as those shown in figure 5. Our present knowledge of the subphotospheric structure of active regions is fuzzy, since the techniques of helioseismology that tell us about this structure do not have high enough spatial resolution. The main reason for believing that the structure has such form is the appearance of the active region in the photosphere shown in figure 5. This appearance typically evolves from many tiny pores early

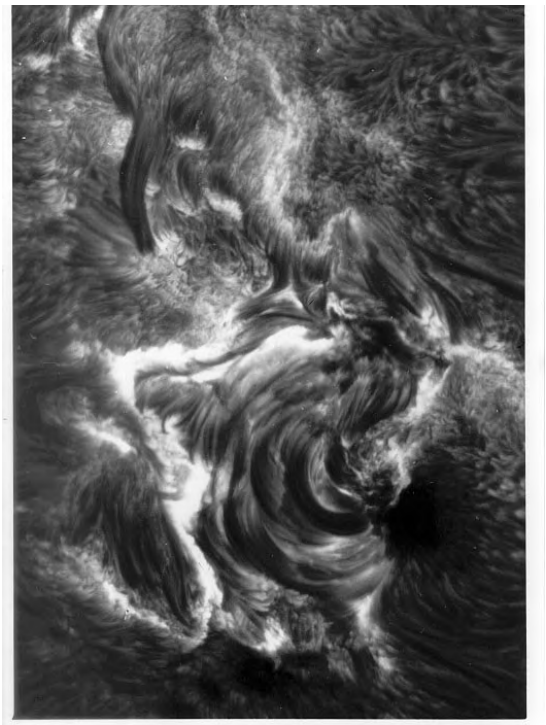

Figure 7. The graceful structures of an active region in the chromosphere, consisting of loops and swirls connecting magnetic features in the underlying photosphere. in the region's life to large spots (in the leading polarity) when it is fully developed. This is understood as the consequence of the gradual rising and emergence of the tree-like structure of figure 6.

In the chromosphere, imaged in the hydrogen Hα line in figure 7, the structure of the active region consists primarily of magnetic loops, which are the continuation of the flux strands into the upper atmosphere from below. Such loops show up in a hydrogen Hα image only where the atmospheric conditions are just right for hydrogen gas to be partially ionized. The temperature in this part of an active region is typically about 10^4 K, and extends a few thousand km above the photosphere. The important aspect of such Hα images is that the structures seen in them outline the magnetic field, since the ionized gas must follow magnetic field lines. Generally, Hα images are more useful for revealing the connections of the magnetic field than for measuring the temperature or density of the gas—brightness in an Hα image has little do do with these thermodynamic variables. An exception is at the footpoints of hot coronal loops, visible in x-rays and not in Hα. Their presence in the corona, overlying the chromosphere, is reflected in the very bright areas that wind through the lower left-hand part of figure 7. In these regions the chromosphere is unusually hot and dense

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

because the overlying arcade of coronal loops that has its footpoints there is also hot and dense. Such active region coronal loops, those with temperatures of several times 10^6 K, appear prominently bright in each of the many active regions in figure 3. Other loops, somewhat cooler, appear in images made in light from spectral lines radiated by ions formed at lower temperatures around 10^6 K, such as that of figure 1.

Evolution of active regions

Active regions are born when strands of magnetic flux emerge into the visible atmosphere from the solar interior. Sometimes flux continues to emerge for as long as 5–7 days, and the active region grows to large size; at the other extreme, flux stops emerging so quickly that observers never even notice the small active region before it vanishes. The shape and brightness of the region depend on both the rate and location of emergence of this new flux and the manner in which it reconnects with the pre-existing magnetic fields. After a lifetime that varies up to a few months, the active region is gradually dispersed by convective motions differential rotation, meridional motion, and magnetic reconnection.

The first indication of an emerging active region is the appearance of bright chromospheric plage in Hα and tiny sunspot pores in visible light. Pores of opposite magnetic polarity are soon seen to be connected by chromospheric loops called arch filaments, which appear as dark linear features in line-center Hα images. The curvature of these features, which are the projections of three-dimensional arches, depends on the angle with which they are viewed. An arcade of several such arch filaments, with bright chromospheric plage at their ends, can be seen in figure 8 (top). These arch filaments are the portions of strands of magnetic flux that are just now emerging into the visible atmosphere, and the pores seen in figure 8 (middle) are the cross-section of these strands where they pass through the photosphere. The image in figure 8 (middle) is made in the blue wing of the Hα line. The chromosphere at this wavelength is transparent when no line-of-sight motions are present, allowing the pores in the underlying photosphere to be seen clearly. However, at the tops of arch filaments, absorption can be seen, as a consequence of Doppler blueshift from their rising motion.

As flux continues to emerge in an active region, pores and small spots tend to coalesce into larger spots, implying that the thinnest flux strands in figure 6 are now above the photosphere, and larger strands of the lower part of the flux rope are now emerging. As long as flux emergence continues, arch filaments can be seen. Often new flux emerges amidst old flux, so only part of the region shows obvious arch filaments, as in the lower part of the region shown in figure 8 (top, middle). The distance separating the opposite-polarity spots of the active region increases. This growth of the active region shown in figure 8 can clearly be seen by comparing the bottom panel of the figure with the two above it, taken a day earlier. Bright loops of comparable size (not shown) can often be seen in x-rays,

overlying the chromospheric arch filament system seen in Hα.

The next phase of the development of an active region is the reconnection of the magnetic fields of the bipole with the ambient fields into which it has emerged. The structure that forms as a result of this reconnection is shown in figure 9, in which a small active region is seen in projection on the solar disk. To understand that structure, it is useful to compare the co-aligned photospheric magnetic field map (left) and projected coronal loop image (right). The polarities in the magnetic field map (toward and away from the viewer) are indicated by black and white; where the field is weak, the map is gray. Note that a strong and compact bipole is present just to the right of the center of the map—black on the left, white on the right. The coronal image shows that the black and white regions of the magnetogram are connected to one another, as one would expect from an emerging bipole. However, there are also prominent connections of the bipole to surrounding regions, forming a structure variously called a pinwheel, anemone or fountain. These loops are formed by reconnection of the bipole, after its emergence, with its surroundings.

The lifetime of active regions, the period for which they can be seen to be bipolar, has no unique or typical value. The most short-lived regions, called ephemeral active regions, and the most long-lived complexes, in which one active region may emerge within another, are discussed elsewhere. Ordinary active regions, as seen on these pages, live from a few days to a few months. The end of the lives is determined by the dispersal of their magnetic flux by convective motions, differential rotation, meridional flows and magnetic reconnection. Bits of magnetic flux break off from the edge of a decaying active region, like icebergs from a glacier. Such moving magnetic features often produce surges as they reconnect with surrounding flux of opposite polarity. Those bits of flux that do not reconnect nearby may be transported great distances. Typically an irregular diagonal streak of such magnetic debris may be seen poleward of decaying active regions. Evidence of such dispersed flux can be seen faintly above some of the northern-hemisphere regions, and below some of the southern-hemisphere regions, in figure 4. Ultimately all such flux reconnects and flows out in the solar wind; new flux in emerging active regions replaces it, and the Sun moves on to its next 22 yr cycle.

Solar Active Regions: Ephemeral

Magnetic flux emerges through the surface of the Sun as bipolar regions with a wide range of sizes, such as shown in figure 1. Larger magnetic bipoles develop SUNSPOTS and are identified as ACTIVE REGIONS. Small bipolar regions, such as indicated in the lower panels of figure 1, are called ephemeral regions, a name given by H Dodson in 1953 because of their short lifetimes. Ephemeral regions have sizes typically less than 20 000 km along their long axis, lifetimes of a few hours, and no sunspots. Their numbers vary in phase with the SOLAR CYCLE. Unlike active regions, which are confined within a latitude band extending from 40°N to 40°S, ephemeral regions occur over the entire solar surface. The bipolar axes of ephemeral regions show all possible orientations, but there is a preference for a proper, low-inclination orientation as seen in larger active regions. During the declining phase of a cycle, ephemeral regions at high latitude (poleward of 30°) develop with a preferential orientation reversed from the active regions and ephemeral regions at lower latitudes. These regions are identified with the new cycle and are seen at least 3 years *before* sunspot minimum and 2–3 years *before* the first recognized sunspot regions of the new cycle.

The amount of magnetic flux that ephemeral regions bring to the surface in one day is equivalent to that in one or more major active regions. Their flux does not accumulate at the surface, however, as the magnetic poles of ephemeral regions quickly interact with nearby magnetic fields leading to the disappearance (also termed cancellation) of one or both of the poles of these ephemeral regions. This interaction results in the complete replacement of the network magnetic fields in the quiet Sun (although not the large-scale pattern of magnetic polarities) within about 40 h, perhaps playing a key role in the heating of the solar CORONA.

General properties of ephemeral regions

Ephemeral regions were first identified in Ca II K images by H Dodson in 1953. Our knowledge about most of the properties of ephemeral regions, however, comes from studies of high-spatial-resolution observations of the magnetic fields on the solar surface during the last two decades. Ephemeral regions are most easily identified in time-sequence magnetograms, where they first appear as two closely spaced positive and negative polarity elements (poles) that strengthen and separate with time. The average flux density in ephemeral regions increases with time, indicating that the magnetic flux in ephemeral regions emerges from below the surface.

Table 1 summarizes the range and average values of the total magnetic flux (i.e. the sum of the absolute values of the positive and negative flux), area, separation of the centroids of the two opposite polarity poles, and lifetime of ephemeral regions.

The lifetime of ephemeral regions, defined as the period both poles can be distinguished as separate elements, strongly depends on the proximity, strength and polarity of the surrounding magnetic elements. During their emergence, the separating poles of an ephemeral region often encounter and 'cancel' with magnetic elements of opposite polarity or merge with elements of the same polarity.

Table 1. Summary of ephemeral region properties.

Property	Average	Range
Total magnetic flux (10^{18} Mx)	9.3	0.1–67
Area (10^{18} cm^2)	0.46	0.1–75
Separation (km)	6910	2200–12 000
Lifetimes (h)	4.4	0.5–140

Orientations

The magnetic axis of an ephemeral region is defined by a line connecting the centroids of its two opposite polarity poles. The bipole orientation of the region is the angle of its magnetic axis with the equator. Ephemeral regions, although they have a wide range in the orientations of their bipolar axes, do show a preference to emerge with a proper, low-inclination orientation. This preference persists throughout a cycle.

The preferential orientation of ephemeral regions follows that of active regions. For the periods when there are two concurrent cycles, the orientations of ephemeral regions are consistent with the preferred active region orientations for those cycles, as discussed in more detail below. The latitude at which ephemeral regions change their preferential bipole orientation coincides with the boundaries separating active regions belonging to different cycles.

Frequency of emergence

The frequency with which new ephemeral regions emerge at the surface ranges from 0.02 to 1 $h^{-1}(10^{10}\ km^2)^{-1}$. These emergence frequencies suggest that thousands of ephemeral regions emerge over the entire surface of the Sun within a 24 h period. With an average flux of 9.3×10^{18} Mx, ephemeral regions can bring to the surface each day from 0.3 to 5×10^{22} Mx, the equivalent of one or more large active regions.

Time variation of ephemeral regions

The number of ephemeral regions present on the visible hemisphere of the Sun at any given time clearly varies nearly in phase with solar activity, as shown in figure 2. The minima in ephemeral region counts precede those defined by sunspots. For example, the minimum in the number of ephemeral regions in 1975 occured about one year prior to the sunspot minimum between cycles 20 and 21 in June 1976; between cycles 21 and 22, the ephemeral region minimum in early 1985 was about 1.5 years before the sunspot minimum in September 1986. By the time of the sunspot minima, the counts of ephemeral regions have increased 40% to 50% above their minimum levels of more

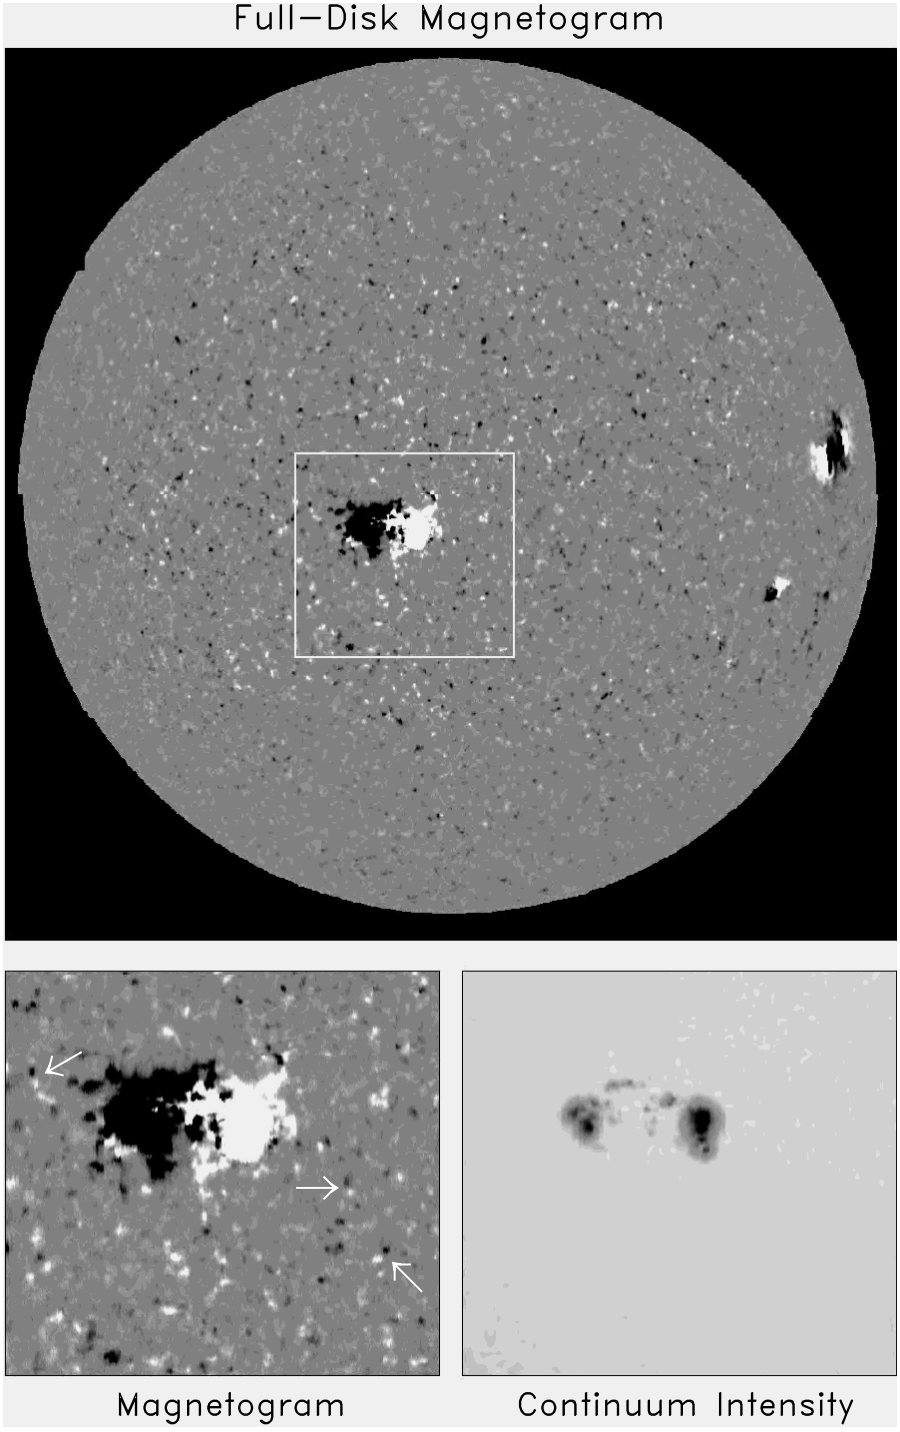

Figure 1. Full-disk magnetogram of the Sun on 25 November 1996 comparing a large bipolar active region and nearby ephemeral regions. The area outlined in white on the full-disk magnetogram is expanded in the lower panels to better show the size comparison and the association of sunspots with a large active region. The horizontal distance of the expanded panels is 3.6×10^5 km. Magnetic fields coming out of the Sun are shown as white and those going into the Sun are black. North is at the top and east to the left.

than a year earlier. In figure 2, the maximum phase for ephemeral regions is reached in early 1978, more than a year earlier than for other parameters of solar activity (e.g. sunspot number) and persists into early 1983. The counts of ephemeral regions also appear to vary on time scales of several rotations in some cases coincident with the pulses

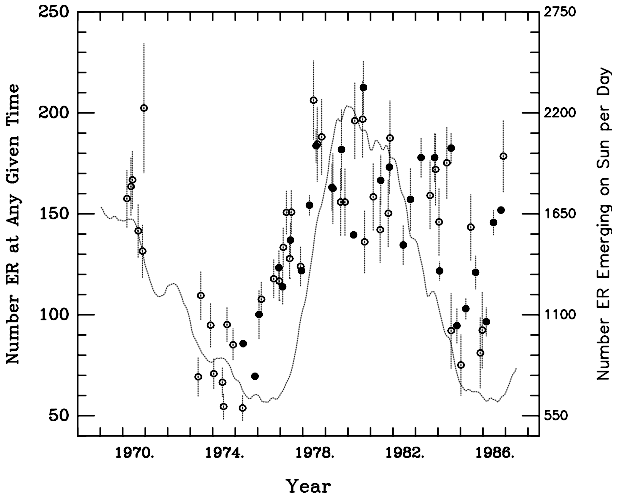

Figure 2. The cycle variation in the number of ephemeral regions observed at any given time (left scale). These numbers are converted to the number of regions per day (right scale) assuming an average lifetime of 4.4 h. The estimated errors, shown by the vertical bars, are derived from the square roots of the number of regions, normalized as per the data points. The smoothed sunspot number (light dotted curve) is shown for comparison.

of activity that are seen in other measures of solar activity, such as the 10.7 cm radio flux.

From the minimum to the maximum phase of cycle 21, the ephemeral region counts increase by a factor of 2.0 to 2.5. This is substantially smaller than the factor of 8 observed for numbers of larger active regions.

If it is assumed that the average lifetime of 4.4 h is valid for any time in the cycle, then the number of ephemeral regions emerging on the Sun per day increases from 870 during their minimum to about 1900 during maximum phase. This range is consistent with the number of ephemeral regions emerging per day determined from their frequency of emergence.

Spatial distribution of ephemeral regions

Ephemeral regions can be observed at any solar latitude. Figure 3 shows the variation in their distribution both in latitude and in relation to larger active regions during a solar cycle. The distribution in latitude of ephemeral regions roughly corresponds to a function that describes how easily ephemeral regions are observed as a function of their distance from the disk center. This correspondence indicates that outside the latitudes where active regions occur, the distribution of ephemeral regions is nearly uniform. There are, however, significant departures that are related to active region belts. The low-latitude peaks in the distribution for 1975 to 1976, for example, coincide with the activity of outgoing cycle 20. At higher latitudes during 1975 to 1978 are peaks in the distributions related to the increase of cycle-21 active regions; these peaks increase in amplitude and shift systematically toward the equator

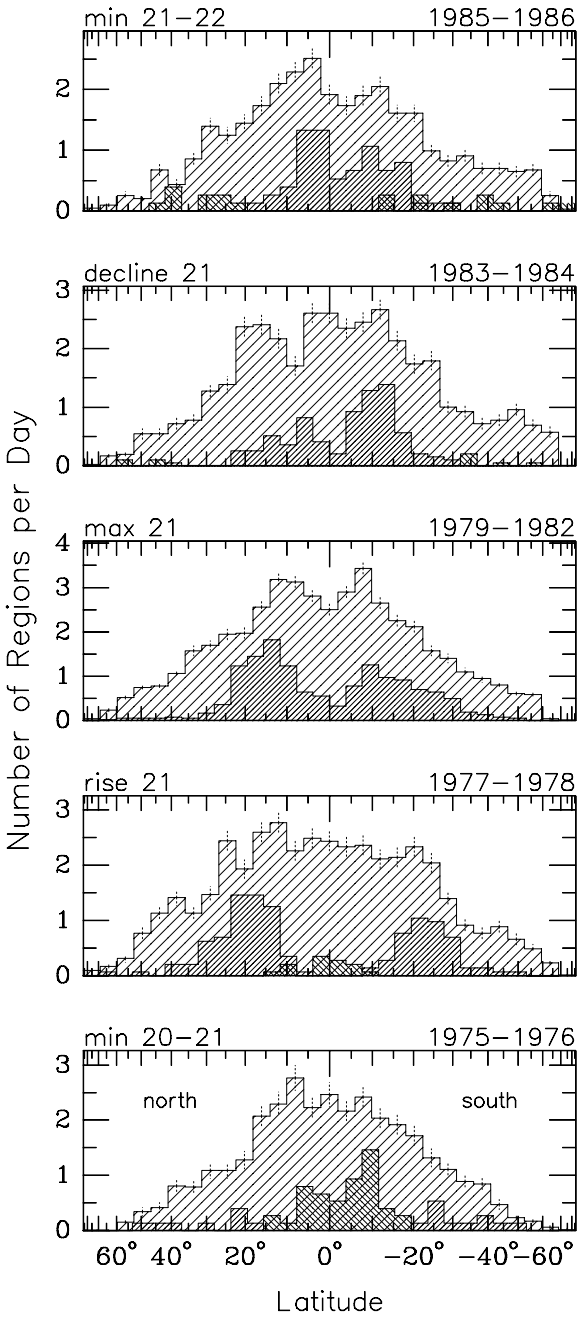

Figure 3. Distribution of ephemeral regions in heliographic latitude during five phases in the rise and decline of cycle 21. The lightly hatched histograms are in equal surface area bins in sine latitude. The more closely hatched histograms, rescaled to fit the plot, are the latitude distributions of active regions for cycles 20, 21 and 22. Cycle-21 active regions have their hatching in the same direction as the ephemeral regions and cycle 20 and 22 regions are perpendicular.

over the cycle, following the emergence pattern of active regions during a cycle.

Two to three years prior to the first appearance of sunspot regions belonging to a new cycle, a

persistent and expanding pattern with preferential reverse orientation ephemeral regions appears at latitudes in both hemispheres poleward of 30°. As shown in both panels of figure 4, this pattern persists and merges with the pattern of new-cycle sunspot regions. As this pattern develops, ephemeral regions at lower latitudes still have a clear tendency for bipole orientations that are proper for the older cycle. The preferentially reverse-orientation, high-latitude ephemeral regions are interpreted to be the first emergence of bipolar regions associated with the onset of a new cycle. The early appearance of new cycle activity in the form of small bipoles (top panel of figure 4) was observed in cycles 19 to 21 as small Ca II K plage regions; these small plage regions are spatially and temporally consistent with the pattern of small reverse-orientation magnetic bipoles in cycles 21 to 23. The high-latitude patterns of ephemeral regions suggest that they are a common feature of solar activity, and they mark the onset of a new solar cycle substantially earlier than would be indicated by sunspot regions. The latitudes and timing of ephemeral regions extends the sunspot butterfly pattern to an earlier time and higher latitudes.

Are ephemeral regions active regions?

There are many similarities between the properties of ephemeral regions and larger active regions strongly suggesting that a substantial fraction of these small bipoles are in fact the small end of a wide size distribution of active regions. The similar preferential orientations, temporal variations and co-spatial peaks in the latitude distribution of ephemeral regions and the larger active regions indicate that these small-scale regions are related to the large-scale emergence pattern of solar activity. Their wider latitude distribution and lower amplitude variation from minimum to maximum suggests that the population of ephemeral regions is a composite of activity related small bipoles and what appears to be a nearly uniform component.

Importance of ephemeral regions to the global magnetic field pattern

Recent observations by SOHO/MDI (Solar and Heliospheric Observatory/Michelson Doppler Imager) indicate that ephemeral regions play a significant role in maintaining the magnetic fields on the solar surface. As ephemeral regions emerge and evolve, their magnetic poles separate and encounter existing magnetic flux. During these encounters, the magnetic fields of most of the ephemeral regions will 'cancel' with opposite polarity magnetic networks, leaving the pole having the same polarity as the network somewhat displaced from the cancellation site. As a result of this process, the magnetic field of an ephemeral region has effectively replaced some of the existing magnetic flux. It is found that ephemeral regions emerge in sufficient numbers to completely replace the magnetic fields in the quiet Sun regions within about 40 h, leaving the large-scale pattern of magnetic polarities unchanged. This 'cancellation' process and the resulting reconfiguration of the magnetic fields (*magnetic reconnection*) can result in localized heating in the chromosphere and corona (see SOLAR CORONA: X-RAY BRIGHT POINTS), and therefore, may be an important source for CORONAL HEATING.

Solar Activity Complexes

SOLAR ACTIVE REGIONS tend to cluster in space and time by emerging in or beside an existing active region or at the site of a previous one. Whereas an individual bipolar sunspot region (see SUNSPOT CLASSIFICATION) typically lasts from a few days to a few weeks—rarely as long as a few solar rotations—a cluster may survive for over a year, kept alive by fresh bipolar regions repeatedly emerging within the small area which delimits the cluster. This tendency has been recognized since the early 18th century but it is only in recent decades that its implications have had an effect on DYNAMO THEORY and on studies of interacting magnetic fields at the solar surface (see MAGNETIC RECONNECTION).

Identifying clusters of sunspot regions

Various names have been invented to describe this phenomenon. Compilers of the *Greenwich Photoheliographic Results* in the 19th century recorded clusters as 'revivals', not mere 'recurrences', of sunspot regions on successive 27 day solar rotations. Recently introduced terms include 'Sonnenfleckenherde' (U Becker), 'complex of activity' (V Bumba and R Howard) and 'sunspot nests' (M Castenmiller, C Zwaan and E van der Zalm). The last of these names was chosen to imply closeness for the emerging bipolar regions and persistence of their rejuvenation far beyond any single region's lifetime. Below, 'sunspot nest' is used chiefly for discussing statistical properties of the clusters and their bipolar sunspot contents, while 'activity complex' is reserved for issues concerning the distribution of magnetic flux in and around clusters.

Statistical methods

Sunspot nests can be identified from tabulations of sunspot positions such as the *Greenwich Photoheliographic Results* by defining selection rules and then applying objective statistical methods to distinguish between real clusters and those produced by chance. Mathematical techniques at different levels of sophistication have been applied to selected epochs drawn from this data base. Several studies, reviewed by C Zwaan and K Harvey, confirm the non-random nature of the space–time distribution of sunspot groups. Basic properties found for nests include compactness (areas much smaller than a medium–large sunspot group, provided that due allowance is made for differential rotation (see SUN: BASIC PROPERTIES) of the nests), ubiquity (at least 30% of all sunspot groups), a steady rate of rotation about the Sun (but unique to each nest) and lifetimes up to about 15 solar rotations (allowing for gaps up to 2.5 rotations). If substantially longer interruptions are allowed, then some nests may even last a few years. There is also a strong tendency for nests to cluster yet again in still larger nests: more than a third of the compact nests are components of composite nests. The components can be quite close in latitude ($<2.5^\circ$) and longitude ($<25^\circ$), although pairs of nests sometimes differ in longitude by as much as 60° to form 'superclusters'.

Other aspects of the clustering phenomenon are revealed from magnetic data of the line-of-sight component of the photospheric magnetic flux, $B_\parallel$ (see SOLAR MAGNETIC FIELD: POLARIMETRY). The daily full-disk magnetograms (figure 1(*a*)) produced at the Vacuum Telescope of the National Solar Observatory (NSO) at Kitt Peak, Arizona (see SOLAR TELESCOPES AND INSTRUMENTS: GROUND), are especially useful in this regard because of their high resolution (1" pixels), high dynamic range (3 orders of magnitude in the magnetic flux density) and high continuity in the flow of data. White patches in figure 1 denote positive (outward-directed) magnetic fields, black patches denote negative polarity. This bipolar signal has an overriding advantage for defining the boundaries of active regions: it makes their evolution and their tendency to cluster much easier to follow from the critical moment of their birth than do, for example, white-light photographs of sunspots.

Thus the 'great complex of activity' enclosed by a box in figure 1(*a*) can be readily decomposed during this particular disk passsage into five individual bipolar regions (A–E), of which three are nested inside one another (figure 1(*b*)). This example also serves to raise a cautionary note about the significance of the word 'complex'. These multiply nested emergences reveal a complicated pattern of polarity reversals. Yet it took a long time after the last emergence to develop *magnetic complexity* of the kind associated with intense current sheets and MHD instabilities resulting in large flares (see SOLAR FLARE MAGNETIC FIELDS). The evidence to date does not favor clustering as the sole process for building up the extreme magnetic complexity of spots classified as a δ configuration. Large δ spots are relatively rare and shorter lived than normal spots of the same size; they seldom last more than one passage across the solar disk. This means that their complexity has, on average, to be produced very quickly, at or even before their emergence.

K Harvey surveyed nearly 1000 newly emerged bipolar active regions larger than 2.5 square heliographic degrees (373 Mm^2) chosen from 29 intervals of above-average continuity in the daily flow of magnetograms at NSO between 1975 and 1986. She found that sunspot nests were rejuvenated by the emergence of new bipolar regions at intervals of, typically, 4–5 days. The number of regions that emerge in nests is comparable with emergences elsewhere in the activity belts: from 40% to possibly 55% of all active regions emerge inside nests. However, the rates of emergence, defined as the number of emergences per day per unit available surface area, differ drastically: new regions are at least 22 times more likely to emerge within existing sunspot regions than elsewhere.

Pictorial methods

A convincing illustration of the clustering phenomenon is made with a stackplot (figure 2), a method first adopted for the NSO synoptic magnetic maps by V Gaizauskas and co-workers. This figure assembles data, separately for each hemisphere, for 100 Carrington rotations (SOLAR ACTIVITY: LONG-TERM RECORDS) during solar cycle 21. It was

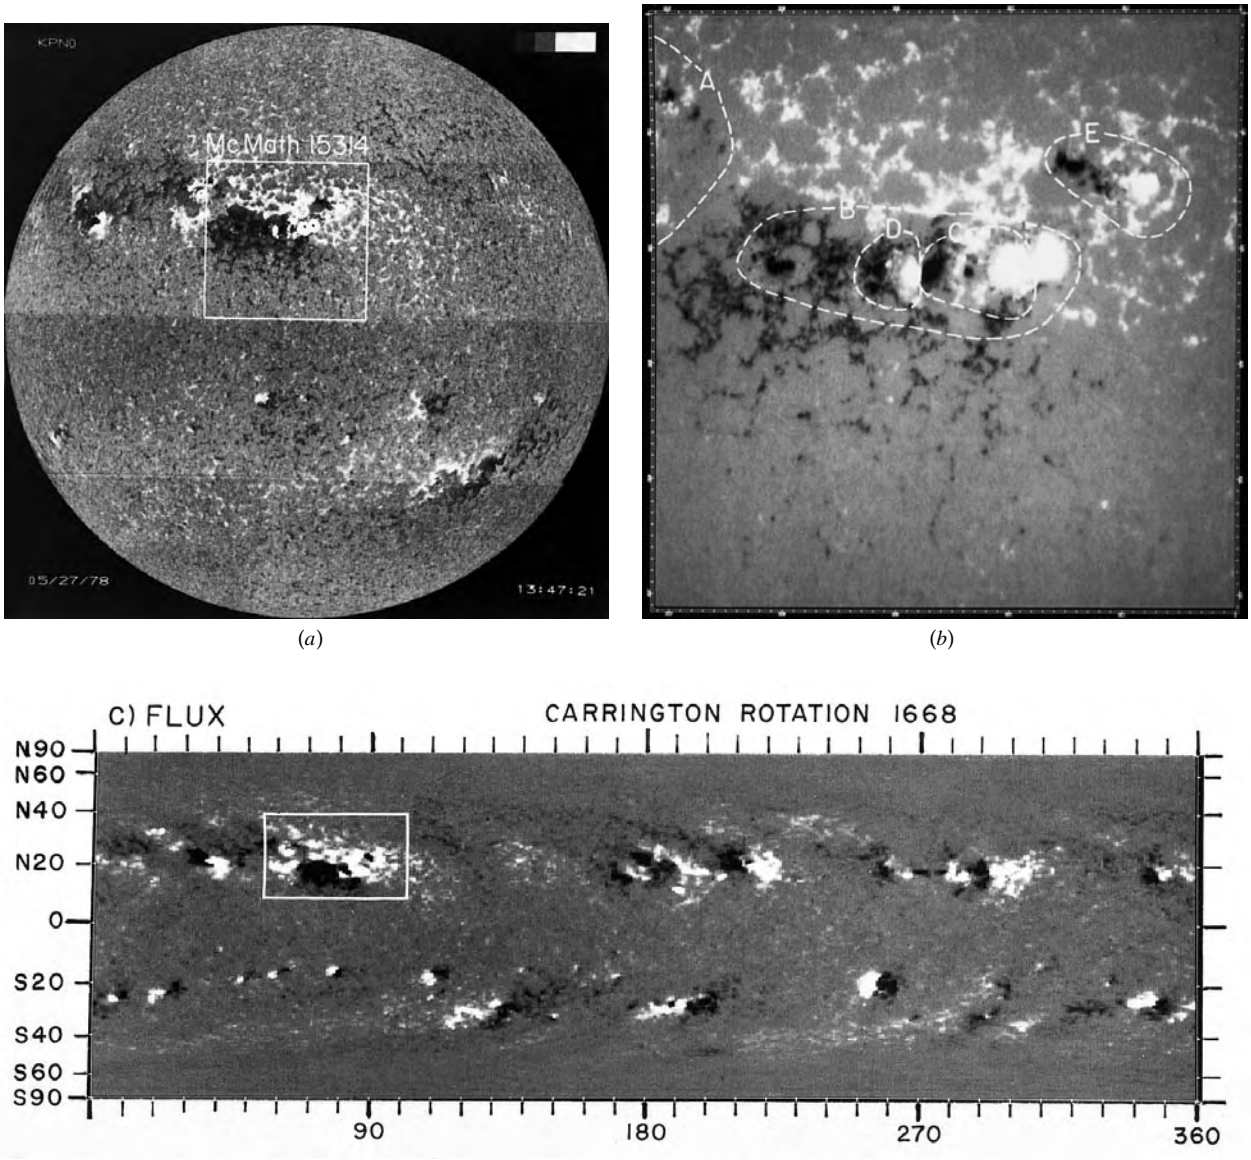

Figure 1. NSO (Kitt Peak) magnetograms and synoptic maps (courtesy of J W and K L Harvey): (*a*) full disk on 27 May 1978 with the 'great complex of activity' boxed in; (*b*) a close-up view of the boxed area ($8' \times 8'$) and with individual bipolar active regions outlined with dashed curves; (*c*) a synoptic map of the magnetic flux density for Carrington rotation 1668; the horizontal scale is the Carrington longitude increasing westward (right), while the vertical scale is heliographic latitude; the rotation begins on the extreme right on 7 May 1978 and ends at the extreme right on 2 June 1978; the white box encloses the same portion of the great complex as panel (*a*) of this figure.

constructed by stacking 30° wide latitudinal strips, one per Carrington rotation, extracted from successive synoptic maps of $B_{\parallel}$ (e.g. figure 1(*c*)). Longitude (L) increases from left (east) to right and extends for another one-third of a rotation to provide continuity for clusters formed near $L = 0°$; time (t) advances downward. In the ~7.5 yr period sampled here the activity belts migrate equatorward from the latitude of 40° used as the maximum of the strips at the beginning of the sample. The central latitude of each 30° wide strip was therefore shifted according to Spörer's law (SOLAR CYCLE) before the data were extracted from the full synoptic maps. The maps are uncompensated for the differential rotation of the Sun; their frame of reference rotates rigidly at the Carrington synodic period of 27.275 days.

In the L–t plane note the linear tracks of different lengths, spacings and slopes which are sometimes double, often diverging, sometimes converging. These tracks locate activity complexes; they share many properties in common with sunspot nests. Thus a nest rotating around

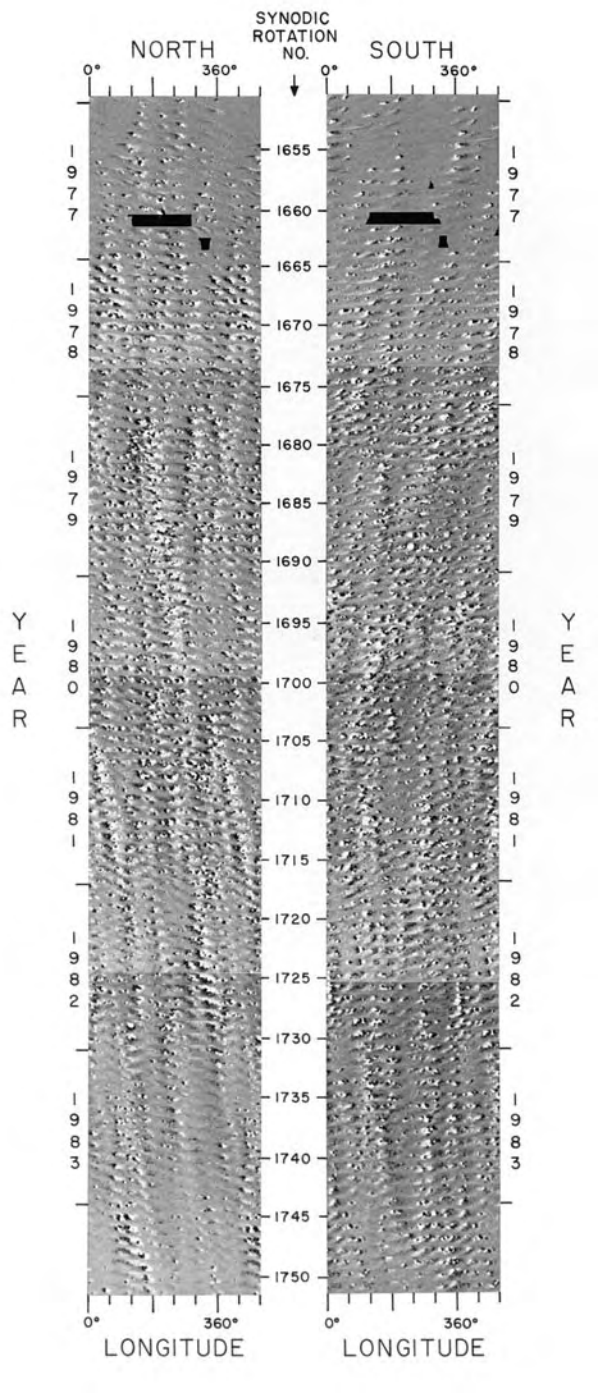

Figure 2. Active belts in both hemispheres of the Sun for 100 Carrington rotations during solar cycle 21. Construction, courtesy of J W Harvey, is described in the text.

the Sun at the Carrington rate produces a vertical track. Nests rotating faster than the Carrington rate produce tracks sloping down to the west (right); nests lagging behind the Carrington rate produce tracks sloping down to the east (left).

The pattern of tracks changes with the phase of the solar cycle—widely spaced in longitude during the onset (1977–1978) and the decay (1982–1983), but more closely packed (1979, N hemisphere) or even chaotic (1979–1980, S hemisphere) during the maximum phase. Even during highly active periods there can be longitudinal zones over 90° wide which are relatively free of activity (centered near 0°, N hemisphere, early in 1980, and near 190°, S hemisphere, in mid-1981). Some complexes are fully active for an entire year (1982, N hemisphere, near $L = 330°$); others fade out after a brief period of recurrent activity only to revive a few rotations later for further lively rotations (1982, N hemisphere, near $L = 120°$).

The existence of so many cohesive tracks enables a number of important inferences to be drawn about activity complexes. They usually appear and end quickly—within 1 solar rotation. The linearity of most tracks means that activity complexes are unaffected by differential rotation over many rotations; only when the injection of fresh flux stops are the weak remnants differentially sheared. Magnetic flux does not accumulate in an activity complex. The 'great complex' depicted in figures 1(*a*) and 1(*b*) had at least 24 additional major bipolar regions emerge within it, for a total of 29, over a period of 6 solar rotations, yet the total flux in the complex remained near a steady level of 10^{23} Mx. During its active lifetime a complex loses as much flux as it gains. The greater part of the flux disappears locally, within the complex; only a minor portion is carried poleward by meridional circulation (see SOLAR PHOTOSPHERE). At times a wavelike pattern of eight regularly spaced bands of alternating polarity is noticeable around the entire Sun.

Very little drift in latitude is evident in complexes or in the tightly bounded sunspot nests. In particular, there is no meridional spreading of magnetic flux across the solar equator during the active lifetime of an activity complex. Hence the term 'active solar longitude', a popular one employed in solar–terrestrial studies, is open to misinterpretation and should be avoided.

Interpretation

The flux densities and spacing of activity complexes have important quantitative consequences for theoretical dynamo models of stars (DYNAMOS: SOLAR AND STELLAR). E N Parker has pointed out that the gaps in longitude between activity complexes are so wide as to limit severely the reconnection between them. So small a portion of the emerging flux is able to reconnect and escape that the surface of the Sun resembles an impenetrable barrier rather than an open surface. The localized disappearance of the surface magnetic flux suggests an active dynamical control by subsurface convection.

The arrival of intense magnetic fields in bursts at a few localized sites has been modeled by Parker as a thermal relaxation oscillator. He conceives an intense azimuthal magnetic field (>3 kG) pressed down into the lower convective zone (SOLAR INTERIOR: CONVECTION

ZONE) by its thermal shadow. The accumulation of heat beneath the field causes the gas heated below to penetrate intermittently through the field, sending thermal plumes of gas with entrained fields to the surface at irregular intervals ∼1 week.

D Wentzel and P Seiden reproduced the quasi-regular distribution of active regions in clusters by using percolation theory. Their model bundles complicated MHD and turbulent processes into two dimensionless parameters: one to express the probability for the release and rise of one flux tube to stimulate the subsequent release and rise of its neighbors; the other to measure the lifetime of flux once it arrives at the surface. Wentzel and Seiden argue that if thermal plumes were the only cause of rising flux tubes, then the resulting surface patterns would not exhibit any of the correlations apparent in active regions. They suggest that flux tubes are released instead by magnetic dissipation of turbulently distorted magnetic fields.

Further progress in elucidating the phenomenon of sunspot clusters awaits helioseismic tomography of subsurface layers of the Sun (see HELIOSEISMIC OBSERVATIONS) with instruments on board the space satellite SOHO (Solar and Heliospheric Observatory) and at the ground-based observatories of GONG (GLOBAL OSCILLATION NETWORK GROUP).

Solar Activity Indices

Solar activity is driven by the temporally and spatially varying distribution of magnetic flux in the photosphere, chromosphere and corona. It covers a range of phenomena at all levels in the solar atmosphere and time-scales ranging from seconds and minutes (SOLAR FLARES and SOLAR CORONAL MASS EJECTIONS), through months (the evolution of ACTIVE REGIONS and SOLAR ACTIVITY COMPLEXES), to the 11 (or 22) yr solar activity cycle. Being able to express aspects of that activity in terms of single indices is useful for studying the Sun's long-term behavior, comparing the Sun with other stars or investigating its role as a driver for various space and terrestrial phenomena. Lang (1995) gives a useful overview of the Sun, its activity and its connection with the Earth. Zirin (1988) provides a more focused discussion on solar astrophysics. Some indices, such as sunspot number, require imaging the solar disk, and, until we can similarly map other stars, are confined to solar applications. Others, such as the Ca II H and K indices or the 10.7 cm solar (radio) flux, are measurements of emission integrated over the Sun's visible disk and are therefore measurable in other stars.

The longest continuous record of solar activity is provided by sunspot counts (*sunspot number*). In 1946 measurements began of another index, the 10.7 cm solar flux. This is more consistent and objective than sunspot number, and so may be more applicable to studies covering the last few decades. More recently, other indices of activity have become available. In this article we will discuss indices of solar activity and the relationships between them. A single index cannot fully describe the level of solar activity. Although the indices discussed here are those which are most widely used, more specialized studies might involve using other manifestations of solar activity as indices. Therefore this discussion should not be regarded as complete.

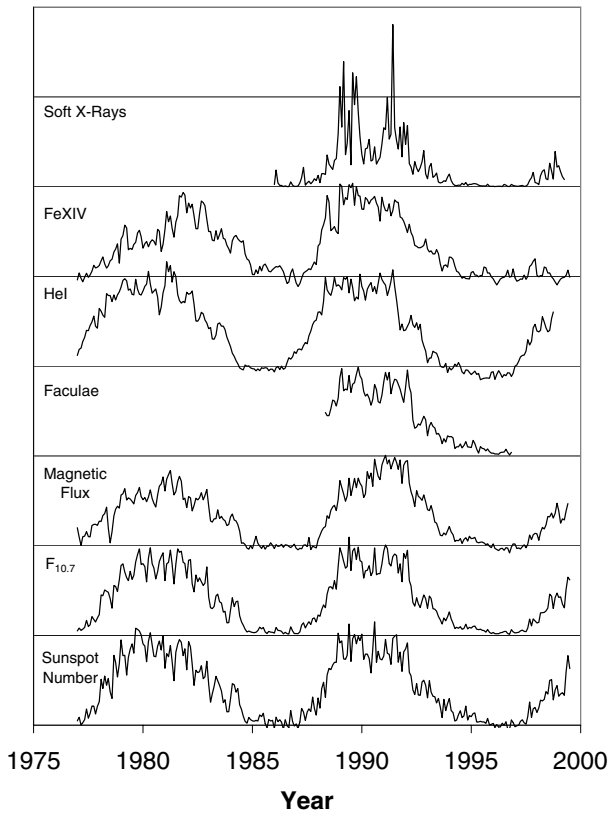

Figure 1. Monthly averages of various indices of solar activity plotted against time for the period 1975–99. Sunspot number, magnetic flux and facular area are indices that are photospheric in origin. The 10.7 cm solar flux is coronal, but is highly correlated with sunspot number, and is therefore plotted adjacent to it. The He I plot is a chromospheric index, and the upper plots (Fe XIV and soft x-rays) describe activity in the corona.

Activity indices

An index of solar activity is a quantity intended to describe some aspect of activity for the Sun as a whole. Although the Sun is highly complex, and we are far from understanding all the processes taking place in the centers where activity takes place, or even the small-scale magnetic and plasma structures within them, similarities and large-scale patterns are present in almost all aspects of solar activity. This is because all manifestations of solar activity are driven by the same 'engine': the temporally and spatially varying distribution of magnetic flux in the SOLAR PHOTOSPHERE, CHROMOSPHERE and CORONA. In principle, determinations of magnetic flux would provide the best general-purpose single index of solar activity. However, this cannot be measured directly. Instead we use as indices of solar activity quantities which are driven or strongly modulated by magnetic fields. By appropriate choices of index we can describe activity at different levels in the solar atmosphere. Figure 1 shows the cyclic variability of several activity indices over the period 1975–99. Sunspot number is a photospheric phenomenon. The 10.7 cm solar flux is coronal, but correlates very strongly with sunspot number. Most active regions contain FACULAE, which are visible in white light, and stand out more clearly with increasing angular distance from disk center. The total facular area is related the total magnetic flux and is therefore a useful index of solar activity. The temperatures (of the order of 10^4 K) and densities of plasma concentrations supported in chromospheric magnetic fields give rise to some useful spectral lines. The lines most widely used as activity indices are the H and K lines of Ca II and Mg II and the 1083 nm line from He I. In the corona, temperatures are of the order of 10^6 K and densities are much lower than they are in the chromosphere. Useful indices of activity are provided by emission lines such as Fe XIV, the 530.2 nm coronal green line and soft x-rays, which are produced by thermal bremsstrahlung (free–free) emission from concentrations of hot plasma. All these indices are strongly modulated by the ebb and flow of magnetic

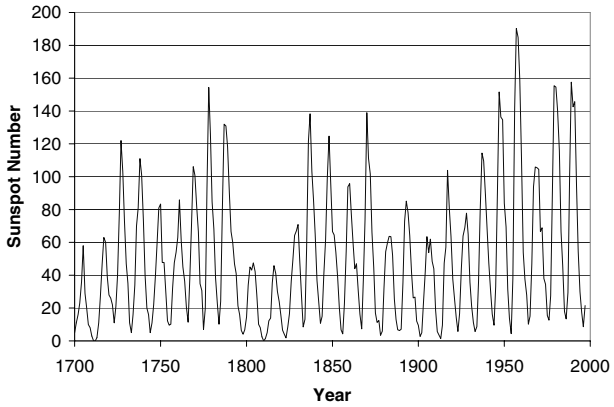

Figure 2. Monthly means of sunspot number between 1700 and present. This is the longest, consistent record of solar activity available. Note the variations in the amplitudes of the maxima and minima from cycle to cycle, and that the cycles vary in length.

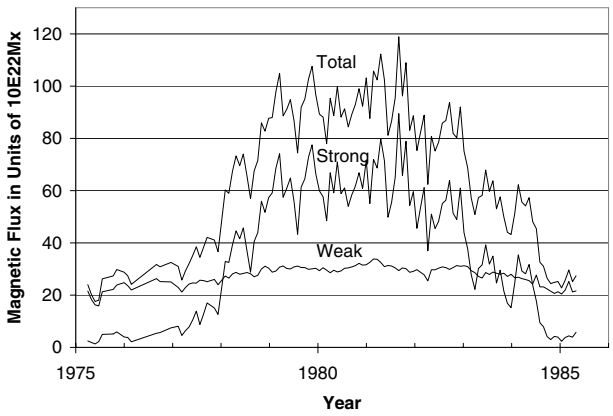

Figure 3. Monthly means of the photospheric magnetic flux over a solar cycle. The upper plot shows the total flux contained in all flux elements, the middle curve the total magnetic flux contained in *strong-field elements*, with average magnetic field strengths stronger than 25 G, and the lower curve, which shows little variation over the solar cycle, the total magnetic flux in *weak-field elements*, where the average magnetic field strengths are less than 25 G ($\text{total}_i = \text{strong}_i + \text{weak}_i$).

flux over the solar activity cycle and remarkably highly correlated, which emphasizes the strong role of magnetic fields in all observable manifestations of solar activity.

Photosphere

SUNSPOTS have been observed since the earliest days of astronomy, probably for more than three millennia. In the Western world they were rediscovered in the 17th century by Galileo and Scheiner. Systematic observations of sunspot number were well under way by the beginning of the 18th century. Schwabe (1789–1875) was the first to identify the 11 yr periodicity in sunspot number. However, these data, available through various sources, were put on a more systematic basis by Wolf (1816–93), who defined the partly empirical 'Zurich sunspot number', given by $R_z = K(10g + f)$, where R_z is the Zurich sunspot number, g is the number of sunspot groups, which are always assumed to contain 10 members, and f the number of single spots. The parameter K, known as the *personal reduction coefficient*, is a scaling factor taking into account the instrumentation, site quality and observer skills and practices for each source of data. In practice, K ranges between about 0.55 and unity. Ideally, there should be no need for parameters specific to individual observatories or observers, i.e. $K = 1$, which is the value Wolf used for his own observations. However, in order to relate modern data obtained using more sensitive instrumentation to older data, lower values of K need to be used. For more information on the history and the scientific background of the sunspot number index, see Zirin (1988), chapter 10, and Wilson (1994), chapters 1, 2 *et seq.*

Despite its rather empirical definition, the Zurich sunspot number (usually simply referred to as *sunspot number*) is a useful index of solar activity. It is monitored at several observatories and yields a continuous record of solar activity dating back at least to the early 18th century (see SOLAR ACTIVITY: LONG-TERM RECORDS). Such timescales are needed for studies of trends in solar activity and in terrestrial CLIMATE studies. Figure 2 shows a plot of monthly means of the sunspot number dating back to 1700. This is the longest, most consistent record of solar activity observations available. It has been possible to extend the sunspot number record back to at least AD 1600. Total sunspot *area* would probably provide a better indicator of total magnetic flux, as would total plage or facular areas. However, these data are not as available as sunspot number. Zirin (1988) reports that, over many years of observations, the solar community has established that a usable estimate of total sunspot area can be obtained by multiplying the sunspot number by 16.7.

Measurements of magnetic field strength at the photosphere are now made routinely by determining the degree of Zeeman splitting of selected photospheric spectral lines. Magnetograms showing the distribution of magnetic flux over the solar disk have been made regularly for roughly two solar activity cycles. Harvey (1994) shows that magnetic elements in the photosphere fall into two broad classes: *weak-field elements*, having average magnetic field strengths smaller than 25 G and *strong-field elements*, where the average magnetic field strength exceeds that value. Figure 3 shows a plot of the total magnetic flux over the solar sphere plotted over a solar cycle, together with the totals of magnetic flux strong-field elements and weak-field elements.

The variation of total magnetic flux over the solar activity cycle shows clearly the ebb and flow of activity and the formation and decay of active regions and activity complexes (these entities are described in Gaizauskas *et al* 1983). However, this occurs almost entirely in elements with magnetic fields stronger than 25 G. When the total

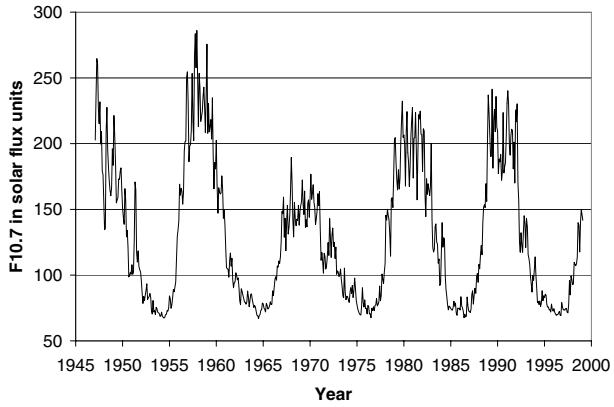

Figure 4. Monthly means of the 10.7 cm solar flux between 1946 and present. With this index the shape of the cycle is much more apparent, and it is possible to see the fluctuations of up to a year or so due to the appearance and decay of complexes of activity. There is a constant background component due to thermal emission from the quiet solar disc, which has a flux density of about 64 solar flux units.

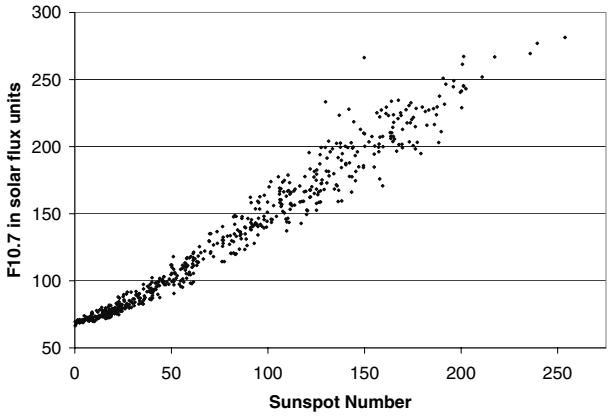

Figure 5. Plot of monthly means of the 10.7 cm flux plotted against similarly averaged values of the sunspot number. The two indices are highly correlated. The reduction in slope for sunspot numbers less than about 30 may be due to low levels of photospheric activity not generating much activity in the overlying corona.

magnetic flux in these strong-field elements is subtracted from the total magnetic flux in all elements, the remainder, which is the total magnetic flux in weak-field elements, shows little variation over the solar activity cycle. Harvey (1994) and Schrijver (1986) note that the total magnetic flux seems to correlate with the total area of active regions, as represented by total PLAGE area and other indices, and that it can be broken into contributions from individual active regions on the basis of their areas.

Chromosphere

Chromospheric activity can be monitored through measurements of the millimeter-wavelength emission integrated over the solar disk. These emissions are purely free–free thermal emission from plasmas trapped in active region magnetic fields. However, because the chromosphere is not much hotter than the photosphere, millimeter-wavelength emission from active regions is only slightly hotter than the background emission from the solar disk. Moreover, atmospheric attenuation makes these measurements difficult to make from the ground on any regular basis. They need to be made from space platforms. The most widely used indices of chromospheric activity are derived from spectral lines. The main ones are the H and K lines of Ca II and Mg II. These have the great additional advantage that they can be used to study chromospheric activities in other stars. Another spectral line widely used for monitoring chromospheric variability is the 1083 nm line produced by He I. This line is purely chromospheric in origin, although there is evidence that this line is 'pumped' to some extent by ultraviolet emission from the corona.

Corona

The slowly varying component of solar radio emission provides an excellent activity index. This emission is best observed in the wavelength range 2–50 cm but shows the largest variability over the solar cycle at wavelengths around 10 cm. It is thermal in origin and is dominated by free–free emission from plasma concentrations trapped over active regions. It also contains a contribution from gyroresonance at low harmonics of the electron gyrofrequency, originating in the corona over sunspots (Krüger *et al* 1985; Tapping 1987; Tapping and Harvey 1994), and maybe some non-thermal radio emission. The 10.7 cm solar flux index, also referred to as F10.7, $F_{10.7}$ or F_{10}, is a measurement of the slowly varying component at 10.7 cm wavelength. Its advantage over sunspot number is that it is an objective measurement that can be made in almost any weather. The monthly averages of $F_{10.7}$ from 1947 to the present are shown in figure 4. It is expressed in *solar flux units*, where one solar flux unit (or sfu) is 10^{-22} W m^{-2} Hz^{-1}. It now forms a continuous, consistent record covering more than 50 yr. In the optical part of the spectrum, the *coronal green line* at 530.2 nm wavelength is a very useful index. This strong emission line is produced by Fe XIV. Other useful spectral lines include Fe X (637.3 nm), Fe XI (789.2 nm) and Fe XIII (1076.8 nm).

Thermal emission in the x-ray wavelength region is significant for plasmas with electron temperatures of 10^6 K or more. This radiation is produced entirely by free–free transitions and is probably the 'purest' index of coronal activity. Its disadvantage is that it has to be measured from space platforms, where it is difficult to obtain long-term, consistent, continuous records. The data here were obtained from the GOES satellite.

Comparing indices

The plots in figure 1 show significant correlations between the indices, despite their being produced at different locations in the solar atmosphere and by different processes. The most striking correspondences are between

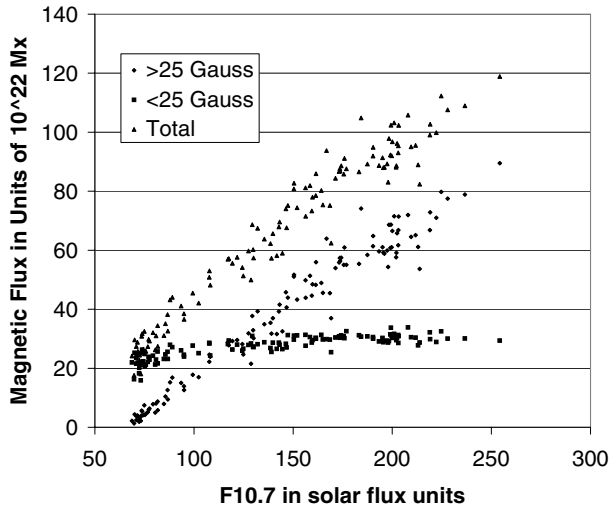

Figure 6. Monthly means of the *weak-field* and *strong-field* magnetic elements plotted against the 10.7 cm solar flux. The *weak-field elements* show no relationship with the 10.7 cm solar flux. However, the correlation with the *strong-field elements* is very strong.

sunspot number, $F_{10.7}$, the He I (1083 nm) line and total facular area. These indices are also highly correlated with total magnetic flux, although rather less so than they are with each other. The Fe XIV line correlates slightly less well (but still significantly), and the soft x-ray flux a little less again. When the short-duration, high peaks are removed, the remaining emission correlates well with $F_{10.7}$ and sunspot number when activity is high, but not when it is low.

Figure 5 shows a plot of sunspot number against $F_{10.7}$. The correlation is high. However, there is a significant decline in the degree of correlation for sunspot numbers smaller than about 30. Figure 6 shows a similar plot of total magnetic flux against $F_{10.7}$. In this case elements of photospheric magnetic flux are divided into two classes: strong-field elements with average magnetic fluxes exceeding 25 G and weak-field elements with average field strengths less than this value. The total magnetic flux from all elements correlates well with $F_{10.7}$, but this variation comes almost entirely from the strong-field elements.

These varying but usually high degrees of correlation can be largely understood when we consider the various levels in the solar atmosphere at which these emissions originate. If magnetic fields are the engine driving all manifestations of solar activity, it is intriguing that the total photospheric flux does not correlate perfectly with sunspot number, $F_{10.7}$ and He I. The not-perfect correlation with sunspot number could be due to not all active regions having sunspots, and the maxima of plage area and sunspot number not occurring at the same time in the evolution of an active region. In the case of indices using chromospheric and coronal emissions, it is possible that not all elements of photospheric flux stronger than 25 G are associated with the footpoints of loops extending into the upper chromosphere and corona and which contain significant amounts of trapped plasma. The indices arise in these trapped plasmas. However, the strong magnetic fields in faculae and especially sunspots form loops extending into the overlying corona over their host active regions. These are good candidates for being plasma traps. This could account for there being a good correspondence to He I and $F_{10.7}$, which originates primarily in the low corona. The soft x-ray flux is an exclusively coronal emission. This emission would only increase when activity extends to those heights. Therefore, we would expect poor correspondence when activity is low, as is observed. The Fe XIV line probably originates lower in the corona, hence the better correlation with other indices over the whole SOLAR CYCLE. The high degree of correlation between the indices, particularly sunspot number, $F_{10.7}$, facular area and He I, indicates that we can use one of these indices as a proxy for the others. For example, for sunspot numbers bigger than about 30, the sunspot number and $F_{10.7}$ are related by $R_z = 1.14 \times F_{10.7} - 73.21$, and $F_{10.7}$ and total magnetic flux can be related through the equation $\Phi = 0.5 \times F_{10.7} - 10$, where Φ is the total (strong-field) magnetic flux in units of 10^{22} Mx.

Discussion

The situation we have with solar activity indices is extremely fortunate for solar researchers. There are indices more-or-less specific to particular levels in the solar atmosphere, which are highly correlated with one another over (with the possible exception of the soft x-ray flux) the full variation in activity during the solar cycle. This would suggest that the emission processes (or mixes of processes) do not change suddenly as activity changes. The other implication is that all the activity indices are strongly modulated by the varying distribution of magnetic flux at and above the photosphere, in a more-or-less simple, linear way, probably in that the magnetic fields support the plasma concentrations producing the emissions forming the indices. If the temperatures ($\sim 10^4$ K in the chromosphere and $\sim 10^6$ K in the corona) vary less than does the density, there is a fairly simple relationship: the more magnetic flux—the higher the density—the brighter the emission.

The ability to summarize the various aspects of solar activity into a single quantity is highly useful. It makes it possible to study the long-term behavior of the Sun, to compare it with other stars and to investigate its role as a driver for processes on the Earth and in space. Considering the rich menagerie of phenomena embraced in the term *solar activity*, is is surprising and fortunate that single-parameter indices have proved valuable in many areas of solar and solar-related research.

Solar Activity: Long-Term Records

Long-term records of solar activity show several interesting features. The most prominent one is the 11 yr cycle that can be traced back in the sunspot record to the 17th century. Indications of longer cycles have also been found, but are difficult to confirm due to the limited length of the observational period. Another interesting feature is the increasing trend of the solar activity between 1700 AD and today. This trend is interrupted by short periods of reduced solar activity around 1900, 1800, and 1700. The last period, called the Maunder minimum (after E W MAUNDER), is by far the most pronounced one and lasted from 1645 to 1715 AD. It is characterized by an almost complete absence of sunspots.

Cosmogenic nuclides measured in tree rings and polar ice indicate that similar minima occurred several times during the past 10 000 years.

When analysing long-term records of solar activity we distinguish between direct and indirect proxies. Direct proxies are continuously or regularly recorded from ground-based as well as from space-borne instruments. In general their quality is high, but limited to the last few decades or centuries. Going back in time the number of continuous direct observations of phenomena related to solar activity decreases. Table 1 provides a list of the main proxies of solar activity that were recorded continuously for at least 50 yr with a time resolution of 1 yr or better.

Table 1. Direct proxies of long-term solar activity.

Solar activity proxy	Records since
Sunspots	∼1600
Aurorae	∼1600
Aa index	1844
Neutrons	1937

Direct proxies of solar activity

SUNSPOTS are the most prominent proxies of solar activity. After the discovery of the 11 yr SOLAR CYCLE by Schwabe in 1843 a well-defined observational program was set up by Wolf leading to the Zurich RELATIVE SUNSPOT NUMBER. Collecting all available information about earlier sunspot observations, Wolf reconstructed the sunspot record back to about AD 1610, the time when the telescope was invented. Pretelescopic observations are only sporadic and limited to relatively large spots. A re-examination based on an extended database of observations agrees well with the Zurich sunspot numbers since 1750, but differs somewhat for earlier times (Hoyt and Schatten 1998).

AURORAE are spectacular colorful phenomena high up in the atmosphere which are mainly visible at high latitudes in both hemispheres (aurora borealis and aurora australis). They are due to ionization processes caused by the interaction of the SOLAR WIND with the atmosphere. Although well known since ancient times their connection to solar activity was only discovered in 1896 by Birkeland. To establish a consistent reliable record is difficult because their appearance is restricted mainly to two oval bands around the magnetic poles that are only sparsely populated (Legrand and Simon 1987). However, many strong individual events are reported that could also be seen in highly populated low-latitudinal areas.

The aa index is a measure of the global disturbance of the geomagnetic field. It is derived from averaged two-hourly measurements at two antipodal stations (see MAGNETOSPHERE OF EARTH: GEOMAGNETIC STORMS AND SOLAR WIND ORIGINS). The aa record goes back to 1844, about the time of the invention of the magnetometer (Mayaud 1973).

The neutron flux in the atmosphere is produced by the interaction of galactic COSMIC RAY particles (protons and alpha particles) with the atmosphere. The primary cosmic ray flux is modulated by the magnetic properties of the solar wind which prevent the low-energy particles from penetrating into the atmosphere. As a consequence the neutron flux recorded by neutron monitors is low during periods of high solar activity and vice versa. The longest record of a neutron monitor goes back to 1951 (Climax, CO, USA, operated by the University of Chicago). It can be combined with the record of the ionization chamber from Cheltenham, which was in operation between 1937 and 1973. In figure 1 sunspots, aurorae and aa index are plotted with an annual resolution. All of them show clearly the 11 yr Schwabe cycle and a generally increasing trend. However, a detailed comparison reveals differences in amplitudes and phases that are due to the fact that, beside observational uncertainties, each solar proxy reflects a different aspect of solar activity.

Indirect proxies of solar activity

High-resolution direct observations of proxies for solar activity are restricted basically to the telescopic era starting in AD 1610. Earlier observations are sparse and usually not very reliable. At present, the only way to extend significantly the history of solar activity is to rely on indirect proxies. Cosmogenic radionuclides such as ^{10}Be and ^{14}C proved to be useful tools for this purpose (Beer *et al* 1990, Stuiver and Braziunas 1993).

Cosmogenic radionuclides are produced by the interaction of cosmic ray particles with the atmosphere. ^{10}Be (half-life: 1.5×10^6 yr) is mainly produced at high energy by neutron-induced spallation reactions on nitrogen and oxygen, whereas ^{14}C (half-life: 5730 yr) is produced by thermal neutrons through the reaction ^{14}N(n, p)^{14}C. The production rate for a particular cosmogenic nuclide j can be calculated for any point D within the atmosphere according to the formula:

$$P_j(D) = \sum_i N_i \sum_k \int_0^\infty \sigma_{ijk}(E_k) J_k(E_k, D)\, \mathrm{d}E_k$$

where $P_j(D)$ is the production rate of nuclide j at position D, N_i the density of target element i, $\sigma_{ijk}(E_k)$ the cross section for the production of nuclide j by the particle k with energy E_k interacting with the target element i and

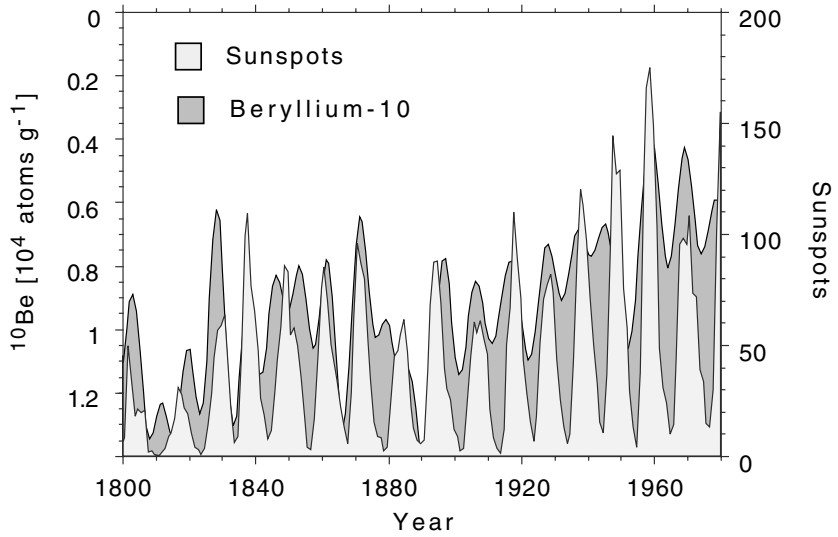

Figure 3. Comparison of the ^{10}Be record from Dye 3, Greenland, with the sunspot record. The time scale of the ^{10}Be record has been shifted by 1 yr to account for the atmospheric residence time.

$J_k(E_k, D)$ the differential flux of particle k with energy E_k at position D.

$J_k(E_k, D)$ can be calculated using a physical model simulating the interaction of primary cosmic ray particles with the atmosphere and the subsequent production and transport of secondary particles in the atmosphere (Masarik and Beer 1999). To describe the dependence of the primary cosmic ray proton flux on the solar activity the following parameterization is usually applied:

$$J(E_p, \phi) = C_p \frac{E_p(E_p + 2m_pc^2)(E_p + x + \phi)^{-2.5}}{(E_p + \phi)(E_p + 2m_pc^2 + \phi)}$$

where $x = 780 \exp(-2.5 \times 10^{-4} E_p)$, $J(E_p, \phi)$ is the proton flux with energy E_p for the solar modulation parameter ϕ, E_p the proton energy, M_pc^2 the proton rest mass (938 MeV) and C_p a normalization factor C (1.244×10^6 cm^{-2} s^{-1} MeV^{-1}). $\phi = 1000$ MeV corresponds to a very active Sun, $\phi = 0$ MeV to a completely quiet Sun. The production rate P depends not only on the solar modulation parameter ϕ but also on the altitude in the atmosphere, the geomagnetic latitude and the geomagnetic dipole moment. In figure 2 the mean global production rate for ^{10}Be is depicted as a function of the solar parameter ϕ and the geomagnetic field intensity relative to its present value. The production rate P is normalized to 1 for $\phi = 550$ MeV and the geomagnetic field 1. During a typical 11 yr Schwabe cycle ϕ fluctuates between 450 and 750 MeV, leading to a mean global peak-to-trough ratio of 1.3 for ^{10}Be and 1.4 for ^{14}C.

After production ^{10}Be atoms in the atmosphere become attached to aerosols and are removed from the atmosphere after a mean residence time of about 1 yr mainly by wet deposition. ^{14}C oxidizes to CO_2 and exchanges between atmosphere, ocean and biosphere with residence times in the last two of about 10 and 60 yr, respectively. To reconstruct the history of production variations natural archives can be used: ice sheets record continuously the ^{10}Be concentration in precipitation and tree rings the ^{14}C concentration in the atmosphere.

Measurements of cosmogenic nuclides in natural archives provide therefore information on several parameters.

1. Changes in the production rate caused either by solar or geomagnetic modulation.
2. Changes in the system itself. Climate changes affect the system behavior. In the case of ^{10}Be they influence the atmospheric transport and deposition processes. In the case of ^{14}C changes in the size of the carbon reservoirs (atmosphere, biosphere, ocean) and in the exchange fluxes between them can occur, affecting the atmospheric ^{14}C concentration.

An interpretation of cosmogenic radionuclide records in terms of solar modulation needs therefore a detailed analysis of all possible involved processes in order to exclude geomagnetic modulation and system effects.

System effects can relatively easily be identified by comparing ^{10}Be with ^{14}C variations. The two radionuclides are very similar regarding production but completely different regarding system effects. Therefore, a comparison using a carbon cycle model allows us to distinguish between production and system effects. The results of several comparisons confirm that both nuclides basically reflect changes of the production rate during the past centuries to millennia.

Information on solar activity derived from cosmogenic radionuclides

The 11 yr solar modulation of the ^{10}Be production rate was found for the first time in an ice core from

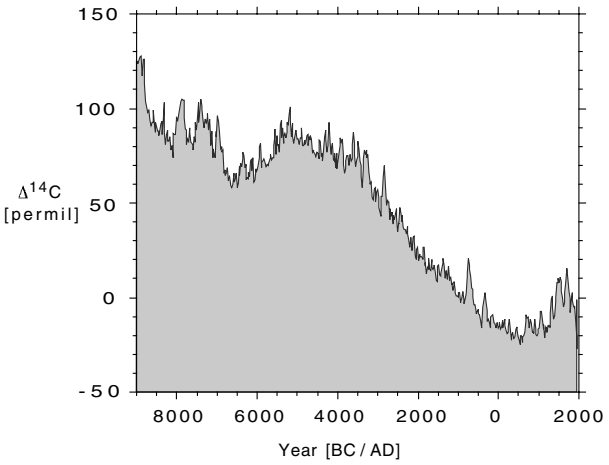

Figure 4. $\Delta^{14}C$ record measured in tree rings for the last 11 000 years. The atmospheric $^{14}C/^{12}C$ ratio was most of the time higher than today owing to a higher production rate. Note the peaks of typically 70–120 yr duration that indicate periods of low solar activity (e.g. Maunder minimum AD 1645–1715).

Dye 3, Greenland, covering the time interval 1423–1985 (Beer *et al* 1994) (figure 3). The comparison of the Dye 3 record with the sunspot record shows in general the expected anticorrelation with a phase lag of 1 yr. The periodicity over the time interval 1423–1985 is 10.83 yr. The Dye 3 record also shows the 88 yr Gleissberg cycle which is difficult to derive from the sunspot record because its length is less than 400 yr. As a consequence of the strong damping effect of the carbon system on short-term variations the most prominent periodicity in the ^{14}C record is the 205 yr De Vries cycle. Longer periodicities, which show up during certain time intervals in cosmogenic radionuclide records, cannot yet be attributed unambiguously to solar activity because they could also be due to changes in the geomagnetic dipole field.

An especially interesting period in the sunspot record is the so-called Maunder minimum (AD 1645–1715). During this time interval only very few sunspots could be observed and the solar activity was very low, leading to an enhanced production rate of ^{10}Be and ^{14}C. Similar minima periods occurred earlier often at intervals of about 200 yr (Spoerer around 1500, Wolf around 1300) and several others are visible in the $\Delta^{14}C$ curve during the last 11 000 years (figure 4). $\Delta^{14}C$ is defined as depletion or enhancement (in per mil) of the atmospheric $^{14}C/^{12}C$ ratio relative to the standard ratio.

The absence of sunspots during solar activity minima does not mean that the solar dynamo was switched off. On the contrary, ^{10}Be shows a clear 11 yr Schwabe cycle during the Maunder minimum (Beer *et al* 1998).

The results obtained so far show that, in spite of the difficulty in separating solar, geomagnetic and climatic effects, cosmogenic radionuclides do have the potential to extend the solar activity record back to several 10 000 yr with a time resolution of 1 yr.

Solar Atmosphere: Empirical Models

The basic atmospheric stratification of the Sun can be described as having (1) an outwardly decreasing temperature with height in the photospheric layers which emit radiation at visible wavelengths, (2) a temperature minimum region where the temperature no longer decreases but begins to increase with height, (3) an extended chromospheric region where the temperature increases to values at which hydrogen starts to become partially ionized and the atmosphere starts to lose energy by Lyman line radiation, (4) a narrow transition region separating the chromosphere and the fully ionized corona, having a large initial temperature gradient near the top of the chromosphere and a smaller gradient at higher temperatures, and (5) the hot ($T > 10^6$ K) corona where hydrogen is fully ionized. See figure 1.

The temperature distribution shown in this figure is for a model of the average quiet Sun and does not represent regions of the solar disk that are brighter and darker than the average, but similar models can be constructed for these other regions. The observed inhomogeneous features on the solar disk include the granular cell and network pattern throughout quiet, relatively undisturbed areas, active regions of varying brightness, as well as sunspots and flares. Significant variations with time occur in such structures, particularly in flares (see PHOTOSPHERE: GRANULATION, SOLAR CHROMOSPHERIC PLAGE, SOLAR ACTIVE REGIONS, SUNSPOT MODELS and SOLAR FLARE MODELS).

To a first approximation, such different types of features can be treated separately, assuming little interaction between the different features, since their horizontal extent is usually much larger than the vertical distance between the photospheric and coronal layers in each case. Hence, it is reasonable as a first approximation to construct separate one-dimensional models that describe the vertical structure of each horizontally distinct region.

Consider a given type of brightness feature in a quiet or active region, such as typical centers of granulation cells or bright network structures, and suppose we have observations of the spectrum of such a feature over a wide range of wavelengths, from the radio region to x-rays. Because the opacity of the solar atmosphere varies with wavelength, we can probe different atmospheric layers by observing radiation at different wavelengths. At wavelengths where the opacity is small the observed radiation originates deep in the atmosphere, and at wavelengths where the opacity is greater the observed radiation originates higher in the atmosphere.

The lowest opacity in the solar atmosphere occurs at $\lambda = 1.6$ μm, the threshold for H^- bound–free absorption. At that wavelength the light originates from the deepest observable layers, and the disk-center brightness is observed to be about 6800 K. The average brightness of the integrated disk at 1.6 μm is about 500 K lower because of limb darkening (see SOLAR PHOTOSPHERE: CENTER-TO-LIMB VARIATION). For infrared wavelengths longer than 1.6 μm the opacity increases as λ increases so that the observed radiation is emitted from higher, cooler layers in the atmosphere, and the observed brightness temperature decreases, reaching a minimum value of about 4500 K at $\lambda = 150$ μm. The opacity continues to increase with increasing wavelength for $\lambda > 150$ μm, and the observed brightness temperature now increases as a result of the increasing temperature in the chromosphere.

Now consider the wavelength region $\lambda < 1.6$ μm. The opacity increases with decreasing wavelength and the brightness temperature decreases, since unit optical depth occurs at successively greater heights. Near 160 nm the brightness temperature passes through a minimum value of about 4400 K and then increases with decreasing λ, again because of the increasing temperature in the chromosphere.

Similar indications of the temperature stratification are evident in the profiles of spectral lines, since the opacity is much greater at line center than in the line wings or the nearby continuum. The Ca II resonance lines have weak emission features near the line centers owing to the chromospheric temperature rise, but this emission varies with time and spatial position and is sensitive to small-scale kinematic effects. The clearest evidence for the chromospheric temperature rise is the increase in continuum brightness temperature in the $\lambda > 150$ μm and $\lambda < 160$ nm ranges and the UV emission lines shortward of 160 nm. These emission lines vary with position and time, but observations at high spatial and temporal resolution (Carlsson *et al* 1997) show that, while the UV line emission varies with time and position, it never vanishes, implying that the chromospheric temperature rise is persistent and not the time average of transitory increases in temperature (see SOLAR SPECTROSCOPY: ULTRAVIOLET AND EUV EMISSION).

However, a problem that is still under investigation is why the strongest lines of carbon monoxide (CO) in the infrared show no central emission. Unit optical depth in these line cores is estimated to occur above the temperature mimimum region (based on results from one-dimensional time-independent, hydrostatic-equilibrium modeling), and these lines are dominated by collisional processes and should be formed in local thermodynamic equilibrium (LTE). Thus the brightness temperature at line center should be the kinetic temperature at unit optical depth. The lowest disk-center brightness temperature in the strongest infrared CO line is about 4100 K (Avrett 1995), but values down to 3800 K are seen near the solar limb (Noyes and Hall 1972, Ayres 1995) (see SOLAR SPECTROSCOPY: INFRARED EMISSION).

An important characteristic of the CO lines is their sensitivity to low temperatures. High-temperature regions along the line of sight tend to be transparent, because CO molecules readily dissociate with increasing temperature. CO observations might be reconciled with the observations of persistent UV line emission if the cores of the strong CO lines are formed no higher than the temperature minimum region, which shows temporal and spatial variations as a result of granulation

and wave motions. See Uitenbroek *et al* (1994). The 3800 K values seen near the limb are more difficult to interpret, however, indicating that the line of sight near the limb passes through cool regions that do not affect the UV chromospheric lines (see CHROMOSPHERE: THERMAL BIFURCATION).

Apart from the unsolved difficulties presented by these CO lines, models corresponding to temperature distributions such as in figure 1 can be constructed for the various brightness components, i.e. for different types of observed features, that roughly account for the entire observed spectrum from each component. Such models are given by Fontenla *et al* (1993) for the average quiet Sun (as in figure 1), for faint and bright components of the cell-network pattern of quiet areas, and for a bright active region. These are shown as models C, A, F and P, respectively, in figure 2.

The temperature as a function of height for each brightness component model has been adjusted so that the calculated spectrum agrees as well as possible with observations. The corresponding density distribution is determined from a balance between gas (and turbulent) pressure and solar surface gravity. The intensity of radiation as a function of wavelength, position and direction and the number densities of atoms, ions, and molecules in various energy states are determined by solving the coupled equations of radiative transfer and statistical equilibrium, accounting for arbitrarily large departures from LTE and arbitrarily large optical depths. The calculations also depend on the use of accurate

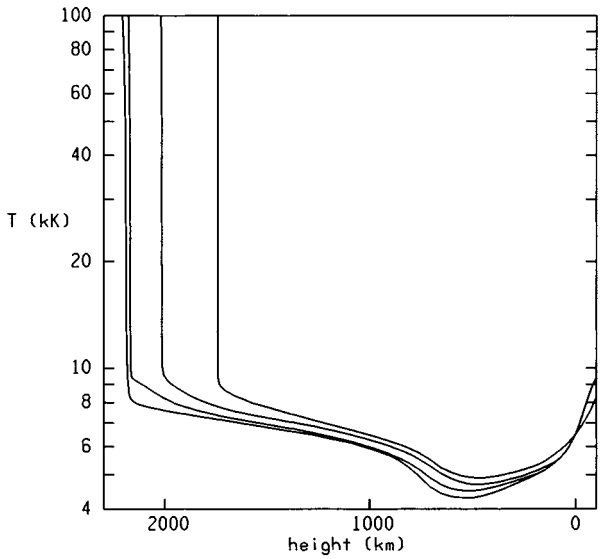

Figure 2. Temperature as a function of height for quiet-Sun models A, C and F and for plage model P (see Fontenla *et al* 1993).

opacities for the millions of atomic and molecular lines throughout the spectrum. See Kurucz (1996, 1997) and SOLAR SPECTROSCOPY: VISIBLE EMISSION.

In addition to the temperature distribution, we assume a microvelocity distribution needed to account for

the observed nonthermal broadening of lines formed at various heights. The same values are used for a turbulent or kinetic pressure contribution to the total pressure. It appears to be sufficient in the various component model calculations to assume that the microvelocity is the same function of density for all models (Fontenla *et al* 1993). Thus the temperature distribution essentially defines each model.

To the extent that the calculated spectrum agrees with observations, we can have confidence that the various models represent the structure of the various components of the solar atmosphere, and we can use the models to understand the physical processes at work. For example, Anderson and Athay (1989) derived the distribution of mechanical heating needed to account for the chromospheric temperature rise in model C (see CHROMOSPHERE: HEATING MECHANISMS).

Spectra computed from component models A, C, F and P agree reasonably well with time-averaged observations of faint, average and bright components of quiet regions and of bright plage regions. As stated earlier, observations of UV emission lines at high spatial and temporal resolutions show that, while there are significant time variations at each position, the UV emission lines never vanish, indicating that the chromospheric temperature rise is persistent rather than transitory.

The narrow transition region separating the chromosphere and corona can be interpreted as the result of (1) sufficient mechanical heating at low densities to heat the corona to the high temperatures at which hydrogen is fully ionized and (2) strong radiative cooling by the hydrogen and helium resonance lines in the upper chromosphere that balances chromospheric mechanical heating, so that the temperature remains in the 8000 K range until the transition region is reached where hydrogen abruptly changes from being mostly neutral to mostly ionized (see TRANSITION REGION MODELS).

The energy required to produce these outwardly increasing temperatures is relatively small. About 10^{-4} of the total energy output of the Sun is needed to heat the chromosphere. The energy required to produce the corona is an order of magnitude smaller, and most of this energy is transported back through the upper transition region by thermal conduction and particle diffusion to be radiated away by the hydrogen and helium resonance lines. The transition region for each of the component models can be determined theoretically by solving the energy balance equations, making use of upper-chromosphere boundary conditions that are determined with reference to observational data. See Fontenla *et al* (1993).

Each empirical model considered here is based on an assumed temperature versus height extending from the deep photophere to the base of the transition region. In principle, an entire spectrum can be computed and compared with observations, and the disparities used to adjust the temperature distribution to get optimum agreement with observations for a particular component region. Given sufficient agreement, such models can provide much useful information about the physical properties of the solar atmosphere.

Time-independent, one-dimensional component models based on observations with low time resolution can only provide information about time-averaged behavior. It is not difficult to construct a series of 'snapshot' models describing the time evolution of the atmospheric region in response to waves or other disturbances. The assumption that different brightness components can be independently modeled, ignoring their effect on one another, is clearly not always valid, as indicated, e.g. by the central brightness temperature of 3800 K observed in strong CO lines near the limb discussed above.

The models in figure 2 indicate that the transition region is located at a height of approximately 2000 km above the photosphere (above the level where the radial optical depth in the continuum at 500 nm is unity). This 2000 km height of the transition region is inferred from the properties of the disk-center spectrum used to define the models. It is important to determine whether limb observations give the same result.

Observations at the limb in the 1083 nm line of He I show a narrow band of enhanced emission at approximately this height. This band of emission can be explained as the result of coronal line radiation at wavelengths below 50 nm, which can ionize He I, illuminating the top layers of the chromosphere. The resulting ionization of He I followed by recombination populates the levels of He I responsible for the 1083 nm emission from these upper chromospheric layers. This interpretation is consistent with the observed property that 1083 emission is diminished in coronal hole regions where the coronal line radiation is reduced. See Zirin (1975) and Avrett *et al* (1994).

For a uniform one-dimensional atmosphere with the transition region at a fixed height, the 1083 nm emission above the limb would abruptly decrease with height after reaching the peak value near 2000 km. However, observations show a gradual decrease above 2000 km (Schmidt *et al* 1994) indicating the presence of chromospheric material at heights above 2000 km.

The 1083 nm line observations at the limb give particularly useful information because this line is strong enough to produce observable emission, but weak enough so that the total optical thickness along a tangent ray passing just above the limb is less than unity, so that this ray can sample the entire line of sight. In stronger lines, such as the hydrogen Hα line, or in the continuum at centimeter wavelengths, the transition region would appear to be located higher owing to the optical thickness of relatively small amounts of chromospheric material projecting above 2000 km in the form of spicules and relatively cool prominence-like gas (see CHROMOSPHERE: SPICULES and SOLAR PROMINENCE MODELS).

Solar atmospheric modeling gives us direct insight into the physical processes that occur in the atmosphere. The spectra calculated from the models also have a

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

practical application. The calculated intensity as a function of wavelength for any particular quiet or active region can be used to fill in the gaps between the relatively few portions of the spectrum that have been observed with high spatial and spectral resolution with good absolute calibration. To the extent that, for a well-defined component region (such as cell centers or bright network features), the calculated intensities generally agree with the available observations over a sufficient wavelength range, the model calculations for the given quiet or active feature provide the absolute intensity versus wavelenth over the entire spectrum at high spectral resolution for that feature.

Variations of solar irradiance are due mostly to changes in the fraction of bright active regions present on the solar disk facing the Earth as a function of time (see SOLAR IRRADIANCE). This fraction varies as the Sun's rotation brings active regions into and out of the hemisphere facing the Earth. Active regions also are responsible for most of the long-term variations of both the total irradiance and the spectral irradiance over the solar cycle. Solar images at a given time at one or more wavelengths (e.g. in the visible) can be used to define the pattern of bright and dark regions. Using the calculated intensity versus wavelength for each region, the disk image can be constructed for any given wavelength (e.g. in the ultraviolet), and we can integrate over the disk to get the spectral irradiance at that wavelength. See Avrett (1998). Such results can provide spectral irradiances on solar-rotation and solar-cycle time scales at wavelengths for which observations are not available (see SOLAR CYCLE).

Solar Chromosphere: Ellerman Bombs

In 1917, Ellerman discovered short-lived, intense brightenings at tiny (<1 arcsec) points in the lower solar CHROMOSPHERE. A typical Ellerman bomb lasts less than 10 min. Its spectrum is characterized by very broad emission wings on the hydrogen Balmer lines. On a photographic negative, the pattern of a bomb's emission resembles a mustache or whisker. Reinforcing the allusion to mustaches is the fact that a bomb's enhanced emission does not extend into the hydrogen line cores. The spectral line then resembles a stripe of shaved skin flanked by two tufts of dark hair. Emission at line center is lacking, presumably because the radiation is absorbed in the overlying atmosphere or in the bomb itself.

Mustaches are about 10% brighter than the continuum at 1 Å from the Hα line center. Because of the strong absorption at the line center, Ellerman bombs must be low in the chromosphere. This is an important difference from flares: all flares are brightest in the cores of the affected spectral lines. Flares are bright because the chromosphere is heated from the overlying corona. The topmost layers are affected first, whereas in bombs, the mustache shape of the spectrum means that the heating must originate in the chromosphere.

Bombs always occur along the boundaries of magnetic field concentrations, so they might be evidence for magnetic field reconnection. They are also interesting because of the resemblance of their extended emission wings to those found in some solar flares. Bombs, which are almost always present on the Sun, may shed light on the elusive mechanism of solar flares.

Bomb sites

Bombs are almost always seen in emerging flux regions (see CHROMOSPHERE: EMERGING FLUX REGIONS) (figure 1) and at the outer edges of SUNSPOT PENUMBRAE (figure 2). There may be as many as 100 bombs per spot group. Very high resolution pictures, such as figure 2, also reveal that Ellerman bombs occur on the network of photospheric faculae (see SOLAR PHOTOSPHERE: FACULAE). The network of bright points extends into the low chromosphere as seen in the figure, and it corresponds to the network of SOLAR PHOTOSPHERIC MAGNETIC FLUX TUBES in the photosphere. Elements of the network brighten about 3 min before Ellerman bomb onset. Thus the true energy source for the explosion may lie in the photosphere.

Ellerman bombs appear before and during the formation of sunspots. In the best images, bright features composed of elements smaller than 700 km diameter can be seen drifting outward from sunspot pores. Bombs probably always occur where magnetic features of one polarity meet other, opposite polarity, features. Roy found that bombs occur only where the magnetic fields are changing and estimated the average rate of flux change at 3×10^{15} Mx s^{-1} (where Mx s^{-1} $= 3 \times 10^{7}$ weber s^{-1}). Bomb frequency and number increase with growth rate of the magnetic field. When bombs occur in clusters, they attain maximum brightness within 2–3 min of each other.

Bomb visibility does not depend on distance from the solar limb, that is, they seem to have the same brightness when viewed from any angle. But near the solar limb bombs are elongated in the radial direction. One study gave the mean length as 800 km and the mean width as 350 km. The maximum brightness and maximum length were achieved at nearly the same time, but the bombs grew only in length at first.

The average lifetime of a bomb is probably less than 10 min, but some bombs last much longer. The longer-lived ones pulsate, so they might be a succession of explosions. Recurrence of bombs in the same location is common. Rust suggested that bombs occur at magnetic field reconnection points, while Kitai suggested instead that bombs occur in isolated flux tubes. An important clue to resolving the issue may be found in the association between bombs and surges.

Hα surges and bombs

Hα SURGES originate in bombs, and surge length (amount of material) is proportional to bomb size times the lifetime, according to Roy and Leparskas. Surges are clusters of very fine dark (sometimes bright) filaments connected to bombs (see SURGES). They consist of dense material apparently ejected from the chromosphere. The velocity averages about 100 km s^{-1}. The trajectories of surge threads above 5000 km match the magnetic lines of force calculated from models of current-free fields in sunspot regions.

No x-ray emission has been clearly associated with Ellerman bombs, but x-ray jets do accompany surges (see SOLAR: X-RAY JETS).

The link between surges and bombs is consistent with a model (figure 3) in which the bomb site lies above a *satellite sunspot*. Satellite sunspots are generally not visible in white light, but they stand out in maps of the magnetic fields surrounding major sunspots. Their polarity is opposite to that of the spot and most of its surroundings. In figure 3, the X marks the supposed site of magnetic field reconnection, and presumably of the bomb itself. One effect of the reconnection is to transfer chromospheric material from lower-lying fields into the higher families of field lines that stretch away from the sunspot. This would explain the surge of material from the bomb site. Numerical models suggest that reconnection should accelerate both hot (x-ray emitting) and cold (Hα emitting) plasmas.

Spectral properties

Severny was the first to study the spectra of mustaches extensively, and he showed that Stark broadening cannot explain the extraordinary extended line wings. Engvold and Maltby measured mustache profiles systematically, finding spectral line widths at Hα ranging from 3 to 10 Å. The true widths could have been greater, having escaped detection because of instrumental dilution.

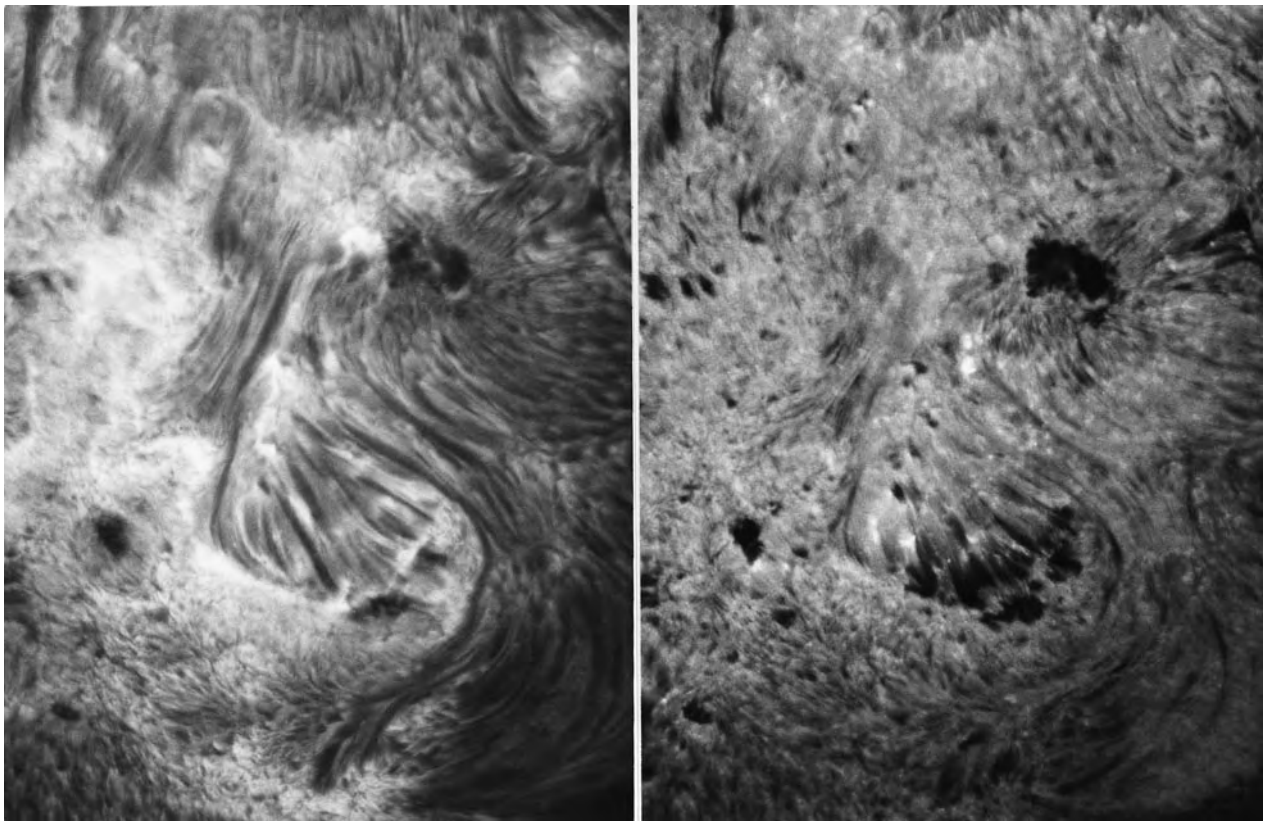

Figure 1. Ellerman bombs in a region where magnetic flux is emerging through the chromosphere. The left and right images were obtained simultaneously through a birefringent filter. The left image shows the upper chromosphere. The dark fibrils in the center are the telltale signatures of emerging flux. The lower chromosphere, on the right, has many bright point-like Ellerman bombs that do not extend into the upper chromosphere. (Sacramento Peak Observatory photograph.)

Bomb spectra are usually asymmetrical, with 60% being brighter in the blue and 40% brighter in the red. But the asymmetry could be due to the effect of overlying material, if there are steady upward or downward flows. During the first 2 min of development, the mean upward velocity deduced from mustache spectra is 8 km s^{-1}. This could account for the blue asymmetry. The mean upward velocity in the underlying photosphere is 1 km s^{-1}, which may indicate that the matter in surges is being supplied from the photosphere.

The spectra of bombs are weakly polarized. Babin and Koval at the Crimean Astrophysical Observatory found 24% linear polarization in the enhanced emission. They subtracted an estimated background from the bomb brightness before computing the polarization degree. From a study of Hα spectra taken simultaneously at four linear polarizations, Babin and Koval also concluded that the degree of linear polarization in any given mustache is the same over the entire emission contour but the orientation of the plane of polarization may be different for adjacent mustaches, and some large mustaches encompass differently polarized elements. Generally, they say the electric vector is perpendicular to the radial direction on the solar disk, but no physical process that could produce such a high degree of polarization was suggested. Another study, at the Sacramento Peak Vacuum Tower Telescope, did not confirm polarization greater than 2%. If a systematic pattern of polarization could be found, it might provide a crucial clue to the physical nature of bombs.

What are Ellerman bombs?

Although the close association of Ellerman bombs with magnetic boundaries suggests strongly that magnetic reconnection is the energy source for bombs and surges, many questions remain unanswered. It is very difficult to explain the great width of the spectral lines, especially since Severny showed that it cannot be due to Stark broadening. That would seem to rule out electric fields, and it casts doubt on the reconnection model.

Shklovskii proposed that the wide wings are Doppler broadened, which implies velocities of several hundred km s^{-1} for the hydrogen atoms. In Shklovskii's model, the radiating matter must be renewed several hundred times. Shklovskii proposed to achieve that with a fusillade of plasmoids from below the chromosphere. His model provides an effective excitation process and explains

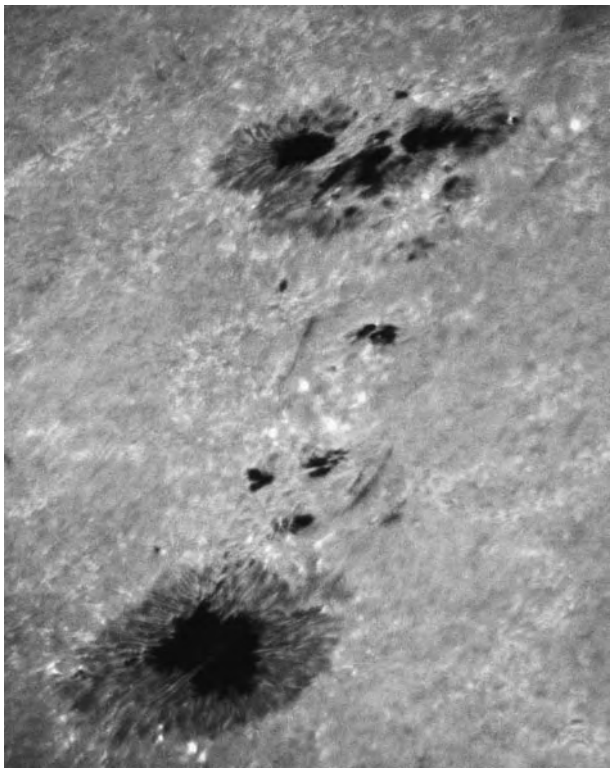

Figure 2. Ellerman bombs at the outer boundaries of sunspots and at the boundary between spots of opposite magnetic polarity (center).

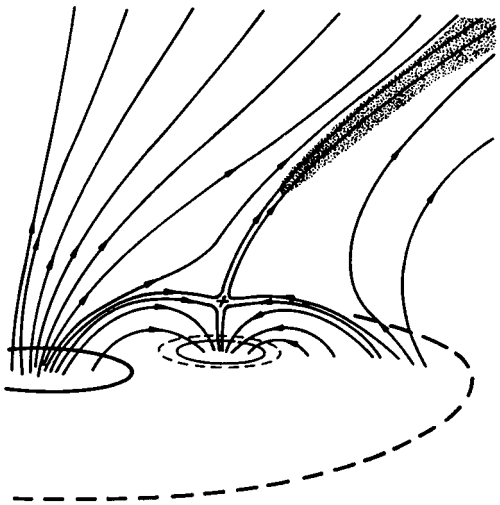

Figure 3. A model of the magnetic field lines above a satellite sunspot. The X marks the point where magnetic reconnection is supposed to heat and/or compress material to give the intense brightening of Ellerman bombs. The shaded feature represents a dark surge of material ejected from the reconnection region.

the broadening. The difficulty is in accounting for the acceleration of the plasmoids.

Another possibility is that the erupting material forming a bomb is driven initially by a Kelvin–Helmholtz fluid instability (see MAGNETOHYDRODYNAMIC INSTABILITIES) at the interface between the chromosphere and photosphere. The focus of this model is more on the steep density gradients and fluid flows at the outer boundaries of sunspots than on the magnetic field configuration. A fluid instability would raise a blob of dense material into the chromosphere where the magnetic fields in it might be pinched off, thus isolating the blob and heating it. The wide spectral line wings would be explained easily because an isolated gas with nearly photospheric density would have very large optical depth in the hydrogen line wings. The problem is to defy gravity and hold a heavy blob up above the photosphere for 5–10 min.

Although they are still not well understood, Ellerman bombs are not much studied today. At one time, it was believed that the extraordinarily wide wings are evidence of previously undiscovered physical processes, and that they are formed at very high densities below an optical depth of 0.4. Today it is understood that a variety of now-familiar phenomena might produce the conditions for broad line wings. Kitai developed a mustache model based on solar flare-like excess heating of 1500 K at heights of 700 to 1200 km above the level of optical depth unity. The principal distinction between his model and flare models is that the disturbance is confined between two chromospheric layers. To reproduce mustache line profiles Kitai had to assume a density enhancement of five in the affected layers, in addition to the heating. The magnetic fields where bombs occur are strong enough to contain the gas at the added pressure, but the problem is to find the heating mechanism. Magnetic reconnection is the best candidate, but no one has worked out a model of reconnection at chromospheric densities.

Solar Chromospheric Oscillations

By the term solar chromospheric oscillations we here refer to any periodic or quasi-periodic dynamic phenomena seen in the solar CHROMOSPHERE. We thus include both propagating and standing waves.

Information about chromospheric oscillations is given by the Doppler shift of spectral lines formed there. To avoid strong temperature sensitivity in the opacity it is also advantageous to study lines originating from the ground state of an element (called resonance lines). Unfortunately, there are only two such lines opaque enough to be formed in the mid chromosphere that are visible from ground based observatories—the two resonance lines from singly ionized calcium called the H and K lines. Much of our knowledge about chromospheric dynamics has therefore been derived from studies of these lines. The H and K lines appear as very strong absorption lines with a slight emission in the line center. This emission has a central reversal such that there are two slight emission peaks with a dark core in between. The peak on the violet (shortward) side of line center is called H_{2V}, the peak on the red (longward) side H_{2R} (and correspondingly for the K line). The calcium H and K emission outlines a pattern strongly correlated with the photospheric magnetic field, the so-called network (CHROMOSPHERE: NETWORK). The dynamic behavior is very different in the network patches and in the inter-network areas and these are therefore treated separately in the following.

Inter-network oscillations

In the inter-network the calcium emission is absent most of the time. When the emission appears it is almost always only the violet peak that appears and in a small area with a diameter of a few arcseconds. Jensen and Orral found in 1963 that the brightening in the emission peak is preceded by a brightening in the line wing that is formed in the photosphere and the phenomenon is often repeated a number of times in the same location with about a three minute period. The localized brightenings are called K_{2V} (or H_{2V}) bright points or preferably bright grains (to indicate that they have a resolvable structure). The quasi-periodic behavior is known as the chromospheric three minute oscillation.

The calcium bright point behavior has been explained as resulting from propagating acoustic waves that form shocks about 1000 km above the visible surface of the photosphere (see figure 1 and Carlsson and Stein 1997). Some aspects of the observed behavior turn out to be very robust diagnostic indicators of the dynamics of the chromosphere. The strongly asymmetric intensity profile with only the violet peak appearing is only possible if there are very strong velocity gradients around the formation height of 1000 km. Such strong velocity gradients typical of shock formation thus have to exist in the solar chromosphere. Acoustic waves steepening into shocks is also the expected behavior from the fact that the gas density falls off exponentially with height in the solar atmosphere forcing a disturbance to grow in amplitude with height in order to conserve energy.

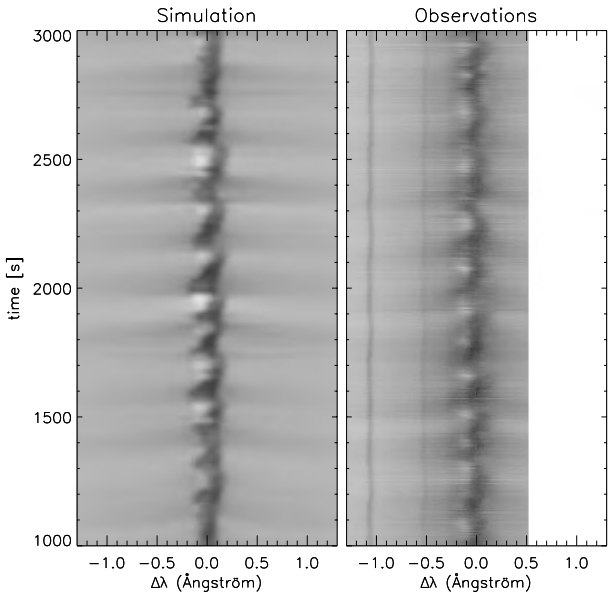

Figure 1. The computed Ca II H line intensity as a function of wavelength and time compared with observations. There is close correspondence between the simulated and observed grains.

The strongly dynamic behavior of the solar chromosphere manifested in the calcium bright grains has important consequences for our concept of the chromosphere. Processes like line formation, line emission and radiative cooling are strongly nonlinear. In a dynamic medium this means that such quantities have to be calculated from dynamic atmospheres; a semi-empirical chromospheric 'average' model (see SOLAR ATMOSPHERE: EMPIRICAL MODELS) will then be misleading.

How are the chromospheric oscillations excited? In a stratified atmosphere like the solar chromosphere acoustic waves can only propagate if they have a period shorter than a characteristic period called the acoustic cut-off period. This period is about 200 s in the solar chromosphere. The acoustic cut-off period is thus close to the three minute period of the dominant chromospheric oscillations. Waves with periods close to the cut-off period can be excited in several different ways and which one is most important in the solar case has been much debated. Long-period evanescent waves will excite wakes with the acoustic cut-off period. Merging of shocked waves with shorter periods will also preferentially favor the same period waves. A sudden pulse with a time scale smaller than three minutes will excite such waves as well. Lastly, in a spectrum of waves with many periods with most power at longer periods, all the evanescent modes will decrease in importance with height leaving the ones close to the cut-off period as the most important ones.

The issue can only be resolved using numerical simulations coupled with observations. From detailed

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

simulations it is clear that the grain behavior is set by acoustic waves that at a height of 280 km above the visible surface have a period of around three minutes. At that height, the velocity field is dominated by the five minute oscillations (see HELIOSEISMOLOGY) but these waves are evanescent and their relative importance decreases with height. These simulations do not, however, give the excitation mechanism for the photospheric three minute period waves. Recently it has been shown (Skartlien 1998) that small collapsing granules, where upflow is turned into downflow in a time scale smaller than three minutes, may be the photospheric excitation mechanism for the calcium grains.

Many more chromospheric diagnostics than the resonance lines from singly ionized calcium are now available thanks to access to the ultraviolet (UV) part of the electromagnetic spectrum from instruments on board satellites and spacecraft. With the SUMER (Solar Ultraviolet Measurements of Emitted Radiation) spectrograph on board the SOlar and Heliospheric Observatory (SOHO) spacecraft much more observational material on solar chromospheric oscillations now exists. The very dynamic behavior of the lower inter-network chromosphere has been confirmed with intensity oscillations and Doppler shifts in general agreement with numerical simulations. The spectral lines formed in the upper chromosphere, however, are not well reproduced by one-dimensional dynamic models. The emission lines in the UV exist in emission all of the time at all locations indicating a mean temperature rise. This may be in the form of magnetic hotter elements overlying the non-magnetic inter-network regions. The UV continua and emission lines from neutral elements show grain-like behavior at all inter-network locations with dominating periods around three minutes. Lines from singly ionized carbon and silicon formed in the upper chromosphere show grain-line variations mainly in Doppler shift with intensity variations of much smaller amplitude than would be the case in a one-dimensional picture. Even a high-temperature indicator like five times ionized oxygen formed in the transition region often shows Doppler shifts well correlated with the oscillations in the lower chromosphere but again with the intensity controlled mainly by processes other than compressive acoustic waves. It is thus clear that the upper chromosphere contains influences from several physical processes. This is also expected from the fact that magnetic fields must start to play a dominant role in the upper chromosphere where the magnetic pressure is larger than the gas pressure. In the upper chromosphere it is thus probably not meaningful to speak about non-magnetic regions any more. The dynamic behavior observable in the calcium resonance lines is, however, evident throughout the chromosphere into the transition region.

The calcium H and K lines are the ideal diagnostic lines available from the ground but there are also other spectral features formed in the solar chromosphere that have received a lot of attention. Examples are the hydrogen Hα line, the calcium infrared triplet lines, the sodium D resonance lines and the helium line at 1083 nm. They all suffer from line formation complexities (like very temperature sensitive opacity, non-locally determined source function or influence from incident radiation field) making the diagnostic inference complicated. Velocities inferred from the calcium infrared lines, the calcium resonance lines and the helium 1083 line seem to be all in phase. In a traditional atmosphere these lines are formed at different heights and the zero phase difference then indicates the presence of standing waves. This has been interpreted as an indication of a chromospheric 'cavity' where reflection off the boundaries set up a standing wave pattern. This picture is, however, in conflict with other observations (like the clear signature of propagating waves seen in the calcium resonance lines).

In addition to the three minute oscillations, recent SUMER observations show oscillatory behavior at shorter periods. Waves with periods around 150 s are seen in upper chromosphere/lower transition region lines. These oscillations can be coherent over thousands of kilometers. They may be correlated with phase jumps observed in the lower chromosphere in the sodium D-line by Deubner and co-workers. The photospheric temperature drop is rather steep and may cause the reflection of waves. A steep temperature rise from the chromosphere to coronal temperatures may also cause partial reflections (around 70% reflection of planar waves in a one-dimensional simplified model). A chromospheric cavity between these partially reflecting may support a velocity field with modal structure even when the transmission coefficient is rather high and the chromosphere is dominated by propagating shocks. Due to the high phase speed of waves with periods just below the acoustic cut-off period of the chromosphere there is less sensitivity to the exact height of the reflecting layer. Such a 'partial' cavity may explain phaseshifts as seen in lower chromospheric lines, the existence of standing wave signatures and preferred periods around 150 s. Modes may also exist due to reflection of waves from shocks.

Network oscillations

The network shows a dynamical behavior very different from that of the inter-network regions. The H and K lines from singly ionized calcium show two emission peaks most of the time. The emission varies with time, but both the red and the violet peak may be missing and the time-averaged profile is quite symmetric. No pronounced three minute oscillations can be found but slower variations around a five minute period are present (Lites *et al* 1993).

SUMER observations give the same picture of mainly slower variations in the network. There are no reported phase relations that would support a picture with upward propagating acoustic waves. It is unclear whether the slow variations are manifestations of waves or of the buffeting of the network magnetic flux tubes by the granular motion. There are some SUMER observations showing three minute periods in network structures but much more rarely than in the inter-network.

Solar Chromospheric Plage

Chromospheric plage (from the French 19th century wording: 'plage brillante', bright plage or bright area) or facular plage (facula, Latin word for small torch) is a bright area seen in chromospheric lines most of the time surrounding one or several SUNSPOTS. Chromospheric plage is one of the main components of the solar activity (see SOLAR ACTIVE REGIONS).

Plages are the results of very complex magnetic processes. After a general description, the magnetic field properties of plages introduce the plage structure. Although very general and simplified, some insight into plage modelization is given.

General description

Chromospheric plages are the prolongation in the CHROMOSPHERE and the TRANSITION REGION of bright faculae seen in the photosphere (see SOLAR PHOTOSPHERE: FACULAE). The linear extension of a plage varies between a few tens of arcseconds to 3–4 arcmin. While the area covered by one plage may vary between less than 1 arcmin^2 and 16 arcmin^2, the total area covered by plages is between less than 1% and 17% of the solar disk area and is strongly related to the solar activity cycle.

In the visible, chromospheric plages are best seen in the strongest lines such as the red H I Hα 656.3 nm line and the blue Ca II H and K 393.4–396.9 nm lines. In the ultraviolet the chromospheric H I Lα 121.6 nm dominates the spectrum, but plages produce enhanced intensities in the entire set of chromospheric emission lines (optically thin or thick). In all the ultraviolet transition region lines the intensity in plages is also strongly enhanced by a factor of 2–20. Chromospheric plages can also be observed in the submillimeter wavelength range (100 μm–1000 μm). In this range, if a 5400 K temperature is assigned to the quiet Sun brightness in the low chromosphere, the corresponding plage brightness can attain up to 6500 K.

Chomospheric plage is the bright part of the chromospheric active region. In the low transition region, where sunspots are not seen, plage fills the whole space of the active region as loops of different temperatures. So, the plage represents an intermediate stage of the magnetic field density, where the flux tube density is not high enough to block the transfer of radiation but large enough to be seen as emissive loops.

The complexity of intermixing of plages with sunspots and filaments in the chromosphere and the transition region is illustrated in figure 1. The fine structure of chromospheric plages observed on high-resolution spectroheliograms shows a fibril-like distribution (e.g. in Hα, Lα) or a distribution of fine grains (faculae) in Ca II K1 (low chromosphere).

The plage area in Ca II K is used as an index of activity and as a proxy component for the modeling of the solar irradiance variation (three components are used to model solar activity variation: sunspots, plages, network).

Magnetic field

Direct measurements of the magnetic field in chromospheric plages have been performed in the H I Hβ 486.1 nm line by using the Zeeman effect. The longitudinal field can reach 80–100 G (1 G = 10^{-4} T) near disk center. New measuring techniques using Stokes polarimetry in Ca II K lines are beginning to provide chromospheric magnetic field values.

The magnetic field of the plage is not homogeneous. It is structured in tubes with a mean flux of 2.5×10^{18} Mx. The filling factor of flux tubes is within the 5–15% range in photospheric layers; this value can be compared with the less than 1% filling factor in a quiet area. From vector magnetogram measurements a gradient of around -3 G km^{-1} with height has been inferred, starting from 1400 G in the middle photosphere. Higher in the atmosphere the magnetic fields from an individual tube spread rapidly with height, producing a 'canopy' of much lower field strengths above the photosphere.

At any time on the Sun a significant part of the magnetic flux defined as the weak fields (flux density below 25 G) comes from a dispersing active region.

There is a strong correlation between the brightness of the Ca II chromospheric plages and the magnetic field strength measured in the photosphere: the Ca II plage bright patches overlie areas of strong magnetic field. The relation between Ca II K intensity and magnetic flux density (measured at photospheric level) holds from the quiet Sun cell network up to the brightest plage. Statistically, the mean trend between Ca II K excess flux density and the magnetic flux density is a power-law relation with an exponent smaller than unity (about 0.6).

The total magnetic flux in a plage is of the order of 10^{22} to 10^{23} Mx. With or without spots the plage magnetic field is bipolar.

The fibril-like structure is related to photospheric magnetic field tubes, filled with matter at relatively low pressure (inside each tube the gas pressure is added to the magnetic pressure to balance the external pressure) and expands and bends with height in a canopy-type structure (see CHROMOSPHERE: MAGNETIC CANOPY).

Plage structure

The plage is the basic element of an active region: plage appears before the sunspots and may disappear long after the sunspots' disappearance. The overall structure of an active region is determined by both the structure of the emerging flux loops and the sign and strength of the fields already present on the surface when it emerges. A plage appears as an emerging flux region sometimes within or near an already existing active region and sometimes in a quiet region. A few hours or a day later, in most of the plages, sunspots emerge within the bright bipolar region. After 3–4 days, the plage has reached its maximum extent (up to 5 arcmin or about 200 000 km across) and intensity in Hα. During the following days (5–15 days) the activity in the plage grows and reaches its maximum. In most cases, after one solar rotation the sunspots disappear and

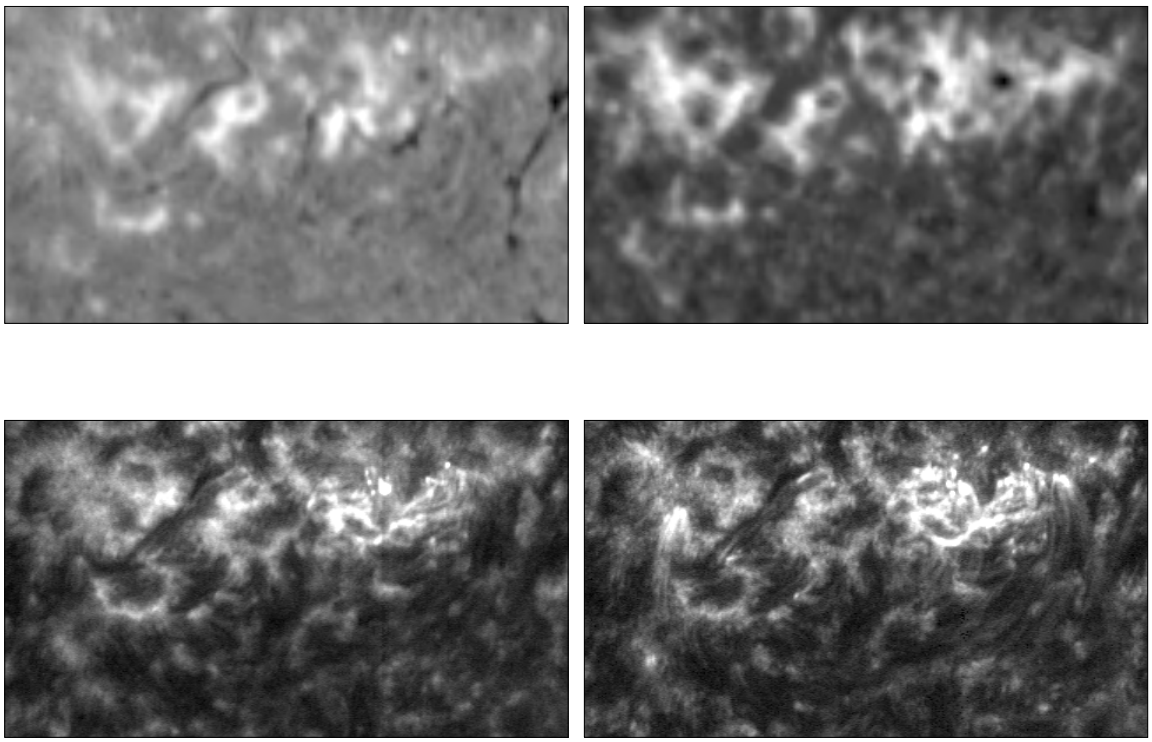

Figure 1. The same active region seen in several lines (8×4.5 arcmin^2). The top left and right are Hα and Ca K spectroheliograms from Sacramento Peak synoptics data (3.8 arcsec pixel size) taken on 13 May 1996 near 13:40 UT. The bottom left and right are simultaneous hydrogen Lϵ and S VI (93.3 nm, 2×10^5 K) spectroheliograms (1 arcsec pixel size) recorded by the SUMER spectrometer on the SOHO ESA/NASA spacecraft taken on the same day near 3:00 UT.

the plage brightness begins to decrease while the size may continue to increase. If the plage is not reactivated by the emergence of a new flux region, the brightness continues to decrease and progressively the plage dissolves in the surrounding network after a few solar rotations (2–4 rotations).

While it is not clear why a plage (or emerging active region) appears in a specific location on the solar surface (although preferred longitudes seem to exist where the plage may emerge), detailed observations of the disappearance phenomenon have been performed. The characteristic diameter of a plage network (or the center-to-center supergranular cell distance) is typically 10 000 km–15 000 km, a factor of 2 smaller than the corresponding quiet Sun network diameter. The following scenario, which combines several processes, has been proposed to explain the decay of magnetic plages:

- from observations using magnetograms and Dopplergrams it has been inferred that flux cancellation often occurs along the cell's boundary when two elements of opposite polarities have approached each other;
- other observations of plage decay suggest that motions along supergranular lanes contribute strongly to the random walk of magnetic features;
- it has also been suggested that retraction, a process that is the reverse of the emergence of magnetic flux, controlled by subsurface motions, contributes substantially to the decay of plages.

At the edge of the plage, where the magnetic flux density is lower than 50–80 G, because of random-walk motion of flux tubes, the plage flux leaks into the quiet region while some flux tubes coming from the quiet region are captured at the plage periphery. The combination of these two processes may explain the slow decay of most of the plages. Some data suggest that less than half of the plage flux leaves the active area; the largest part disappears *in situ* by reconnection, cancellation or submergence.

Plage flux tubes are filled with matter in motion. From the chromosphere to the low transition region (6000 K $\leq T \leq 2 \times 10^5$ K) the velocities increase from a few km s^{-1} to 25–30 km s^{-1}. There is a systematic redshift detected over plages in the chromosphere transition region. It is more important than in the quiet Sun and the velocity differential, compared with the quiet region, peaks at 7 km s^{-1} near 10^5 K. In the transition region, in lines with a maximum of the ionization temperature near 10^5 K, along individual loops, velocities reaching up to 60 km s^{-1} have been measured (e.g. from SOHO, the Solar and Heliospheric Observatory). These results must be confirmed by several other measurements to evaluate the importance of flows

in plage loops. There are still uncertainties in the interpretation of such Doppler velocities:

- either the flow is coming up from one loop leg and returning down to other loop leg,
- or the apparent Doppler shift is due to the propagation of sound waves, Alfvén waves, or magneto-acoustic waves along the loop magnetic field.

Few measurements of chromospheric plage oscillations have been done. Although 5 min intensity and velocity oscillations in phase over an extent of 10–20 arcsec have been reported, the amplitudes are smaller than in the quiet area and an increase of power has been noticed for periods shorter than 100 s.

The complexity of active regions, a mixture of very compact clusters of magnetic flux tubes (sunspots) and more dispersed flux tubes (plage) of several polarities, arises from the mutual interaction of new flux loops rising within and near old ones. Within a few hours the whole magnetic flux tube distribution is renewed.

Modeling of plage

The solar abundance in the quiet solar photospheric region is used as a reference for abundance determination in different structures at several temperatures. Measurements made in using the intensity of lines formed in the 2×10^4–10^5 K temperature range indicate a possible enhancement of low first ionization potential (FIP) (smaller than about 10 eV) elements compared with the photospheric abundance in plage. The presence of electric fields in this highly dynamic atmosphere has been proposed as the cause of the enrichment of low-FIP elements.

Semiempirical models of plage in one or two dimensions have been built. Such models provide a first estimate of temperature and density distribution as a function of an average height. From the top of the photosphere the plage temperature is higher than the quiet Sun temperature and, above the minimum the temperature gradient is increasing faster, giving a more compact chromosphere. In the chromosphere the electronic density is higher than the corresponding quiet Sun density. While in the quiet Sun the chromospheric plateau has an electronic density of a few 10^{10} cm^{-3}, the chromospheric plage plateau reaches a few 10^{11} cm^{-3}. At the top of the chromosphere the total pressure is greater than 1 dyn cm^{-2}, nearly 10 times the pressure of the quiet Sun. On average the plage chromospheric radiative cooling is about 5 times that of the quiet Sun.

Several dynamical models have being proposed to explain the emergence and decay of active regions (see CHROMOSPHERE: EMERGING FLUX REGIONS).

Solar Constant

The amount of radiant solar energy per second arriving perpendicularly on an area of one square meter, at a distance of 1 astronomical unit from the Sun. It is equivalent to the average flux of solar radiation at the top of the Earth's atmosphere. The measured value of the solar constant is 1368 W m^{-2}.

Because the Earth travels round the Sun in an elliptical orbit, its distance from the Sun ranges from 1.0167 AU to 0.9833 AU. Consequently, over the course of a year, the flux of solar radiation at the top of the atmosphere varies about its mean value by about $\pm 3\%$. Precise measurements of the solar constant have shown that the luminosity of the Sun fluctuates on time-scales of days and weeks by up to 0.2%, mainly as a result of changes in the numbers of dark spots or bright faculae on its surface. Long-term measurements suggest that there is a general variation in solar luminosity that appears to follow the solar cycle, the Sun being about 0.08% more luminous at solar maximum (when there are more active regions on its surface) than at minimum.

Solar Corona: X-ray Bright Points

X-ray (or coronal) bright points are small knots of intense x-ray emission scattered randomly throughout the solar CORONA. They are associated with pairs of opposite-polarity magnetic flux seen below in the SOLAR PHOTOSPHERE and are most likely to be heated by the motion of the magnetic fluxes causing reconnection in the corona.

Observations

In the late 1960s and early 1970s rocket-borne X-RAY TELESCOPES capable of resolution and pointing stability in the arcsecond range imaged the Sun for between 5 and 15 min per flight. These images taken using very similar grazing incidence techniques to those used today revealed the complex beauty of the solar corona and revolutionized our understanding of it. One particular rocket flight on 8 April 1969 took longer time exposures than previous flights and revealed for the first time hundreds of small faint spots of emission scattered randomly across the disk; they were named x-ray bright points. However, it was not until the SKYLAB mission provided consecutive images over a period of hours and days that the characteristics of bright points could be studied. From these images it was found that x-ray bright points are made of a diffuse cloud of emission which grows at about 1 km s^{-1} up to approximately 22×10^3 km in diameter and contains an intense bright core about $(3–4) \times 10^3$ km across. Their sizes were determined to range from 5×10^3 to 20×10^3 km, however, the lower bound to this range was limited by telescope resolution and the upper bound was arbitrarily chosen so that the bright points could be distinguished from ACTIVE REGIONS with which they appeared identical from coronal images. It was found that the lifetimes of bright points varied widely from 2 h to 2 days which is considerably shorter than for active regions. Recent high-cadence observations, however, have discovered x-ray bright points with lifetimes as short as a few minutes. These bright points are normally just a few arcseconds across (2×10^3 km) and are known as micro bright points.

X-ray bright points have fairly low temperatures of about 2×10^6 K but high electron densities of around 5×10^9 cm^{-3}. They appear randomly distributed throughout the corona in coronal holes, quiet regions and active regions. Approximately 400 are present at any one time at solar minimum with approximately 1200 appearing each day, although these numbers vary depending on the wavelength, cadence and resolution of the telescope used.

Comparing the first rocket images with magnetograms it was found that bright points were associated with pairs of opposite-polarity magnetic fragments. Since ephemeral regions, pairs of newly emerged opposite-polarity flux, had just been discovered it was natural to assume that bright points were caused by the new emergence of a small loop in the corona. However, studies of the long-term variation of bright points revealed that their number decreased near solar maximum, suggesting that they were out of phase with the solar cycle. This was in complete contradiction to the observations of ephemeral regions which were found to be in phase with the solar cycle.

This discrepancy remained a mystery for many years basically because after Skylab soft x-ray images could only be taken on board rocket flights and so further comparative studies could not be made until it was discovered that He 10830 dark points observed by ground-based telescopes were fairly good proxies for the 30% largest bright points. A ground-based study comparing He 10830 images and magnetograms then came up with an explanation in 1984. This detailed study of time sequences of magnetograms revealed that most pairs of opposite-polarity flux below dark points were in fact converging not diverging and that the pairs of magnetic fragments were mutually losing flux. These new photospheric phenomena were called cancelling magnetic features and are believed to be related to the amount of mixed-polarity flux in the photosphere which decreases by a factor of 6 from solar maximum to solar minimum. Thus, like x-ray bright points, cancelling magnetic features were also found to be out of phase with the solar cycle. Indeed, recent studies show that about 80% of bright points are associated with cancelling magnetic features and just 10% with emerging flux regions. The remaining 10% are mysteriously related to unipolar regions of flux, although with higher-resolution instruments it may become apparent that these unipolar regions actually contain weak opposite-polarity regions of flux after all.

Interestingly these recent studies also suggest that bright points are in fact neither in nor out of phase with the solar cycle, but that their number remains approximately constant over the whole cycle. The change in opinion has come about through results from soft x-ray telescopes with much less scatter than Skylab which reveal that the intense emission from active regions can obscure the faint bright points during periods of increased activity on the Sun and so make it appear that at solar maximum there are far fewer bright points.

A study in the late 1970s using a time series of Fe XV images from the S-082A instrument revealed that x-ray bright points consist of small loops which vary in intensity on a timescale of about 6 min. The loop structures were found to be quite complex in nature and had loops of different temperatures. This was believed to be consistent with the repeated impulsive heating of the loops followed by their subsequent cooling before another pulse of heating. It was also found that sometimes these fluctuations could increase by a factor of 10–100. In such cases the bright point was said to have flared. These microflaring events tend to occur in about 10% of bright points and generally last from 5 to 10 min. Occasionally when x-ray bright points flare they produce long hot loops that grow up to hundreds of megameters long at speeds of 1000 km s^{-1}. These events are known as SOLAR X-RAY JETS. In bright points the jets are mostly two winged.

X-ray bright points and bright point flares have typical energy emissions between 10^{26} and 10^{29} ergs and

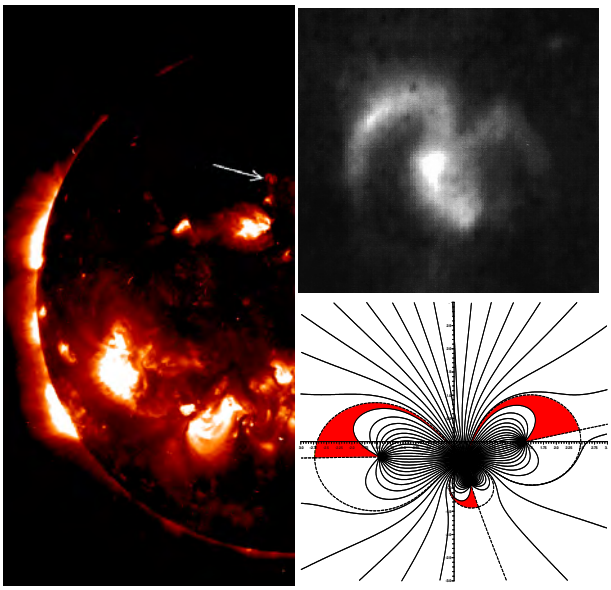

Figure 1. Left: half of a full-disk soft x-ray image taken by NIXT. The arrow indicates a bright point which is enlarged at the top right. Bottom right: the magnetic field due to the fragments below the bright point. The shaded regions are the newly reconnected field lines that give rise to the bright point.

so are the size of microflares. Indeed, signatures of microflares can be identified in the GOES data coincident in time with some of the larger bright point flares. Bright points also produce radio emission that can be both thermal (e.g. 17 GHz, 20 cm, etc) and non-thermal (e.g. type III bursts) suggesting that there are both open and closed field lines and that whatever powers bright points is not just heating them but is also accelerating particles.

An interesting phenomenon relating to cancelling magnetic features has been observed in Hα images: tiny filaments form above the cancelling magnetic feature. They typically last between 10 min and a few hours before they erupt. It is estimated that about 10% of cancelling magnetic features may have associated filaments, but there have, as yet, been no studies relating bright points or bright point flares to these filaments or their eruption.

Further studies of x-ray bright points using high-resolution soft x-ray telescopes (for instance, NIXT and TRACE) have managed to resolve the structure of bright points. Many are just single loops, but others are more complex and have a multiple loop structure (figure 1). In general, the complexity of the x-ray emission is related to the complex mixture of magnetic polarities below.

Theory

It is believed that x-ray bright points are heated by driven reconnection: the motion of footpoints of magnetic loops that are pushed together, interact and reconnect in the corona. The generally accepted model is the converging flux model proposed in 1994 which predicts in a natural way the key observations relating to x-ray bright points and their associated cancelling magnetic feature. In this model the interaction of two opposite-polarity magnetic fragments in an overlying ambient field are modelled in three stages: the pre-interaction phase, the interaction phase and the cancellation phase (Figure 2). First, in the *pre-interaction phase* of the model, a positive and a negative fragment are situated in a uniform overlying field such that they are unconnected magnetically, analogously to the observation that before opposite polarity flux pairs in a cancelling magnetic feature start to cancel no fibrils are observed linking them.

These opposite-polarity flux regions are seen to converge slowly at a typical speed of 0.3 km s^{-1}, which compared with the Alfvén speed of 100–1000 km s^{-1} is very slow; thus in the model the magnetic field is assumed to be evolving through a series of quasi-static equilibria as the fragments converge. The observations show that at some point during the convergence a bright point will appear (not necessarily directly) above the pair of opposite-polarity flux fragments. This sudden appearance of the bright point marks the start of the *interaction phase* and is explained naturally in the model as the point at which the fragments first interact magnetically at a neutral point which forms in the photosphere. The field is assumed to continue to evolve through a series of equilibrium states as the fragments converge even more closely; thus reconnection must take place at the neutral point. The reconnection causes field lines to be 'broken' and new field lines to be formed. Although initially the neutral point and therefore the energy released in the model start out at the level of the photosphere as the fragments continue to converge the neutral point rises up into the corona. Newly reconnected field lines are believed to be injected with hot dense plasma which creates the increased emission observed in soft x-rays as the bright point.

Observations show that bright points start before cancellation starts and may even end before cancellation starts. In the model this is also true: at the point where the fragments first interact magnetically they are not actually losing flux, merely changing their flux connections. The bright point will continue until the two fragments are completely connected magnetically. This point may be reached before or after the two fragments actually touch one another in the photosphere. At this point the *cancellation phase* begins even though the interaction phase may not have ended. Flux is lost mutually from each fragment through reconnection in the photosphere. This process can continue until either the smallest fragment has been completely cancelled or the flows driving the two fragments stop driving them together.

The converging flux model clearly explains the 80% of bright points that are associated with cancelling magnetic features. The 10% associated with the emerging flux regions can also be explained by just considering the stages of the converging flux model in reverse (i.e. considering a diverging flux model). The cancellation phase if run backwards is analogous to an emerging phase where two new fragments grow in strength and diverge, as observed.

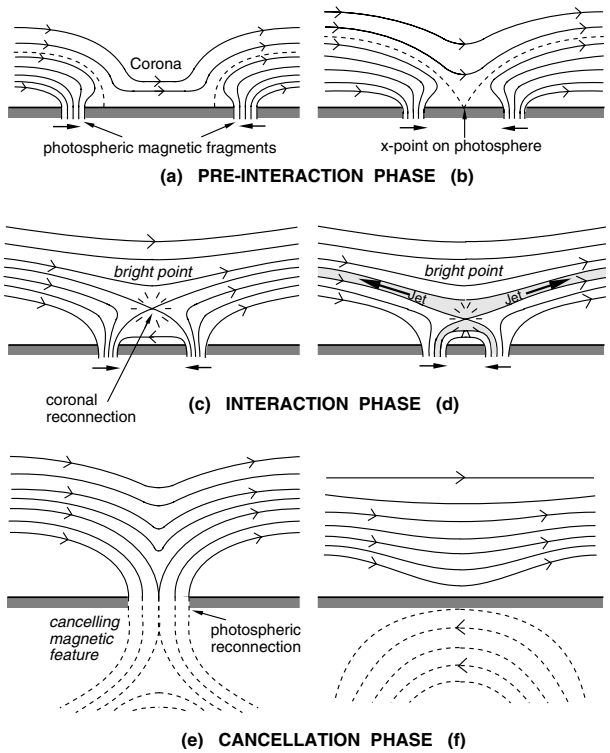

Figure 2. Converging flux model. (*a*) and (*b*) show the *pre-interaction phase* where the fragments are initially unconnected. (*c*) and (*d*) show the *interaction phase* in which reconnection creates a bright point in the corona. (*e*) and (*f*) show the *cancellation phase* where photospheric reconnection forms a cancelling magnetic feature.

This may or may not, depending on the circumstances, overlap with the interaction phase which as before gives rise to reconnection in the corona that creates the bright point. This time, however, the reconnection is driven by the divergence of the fragments. The bright point ends when the two fragments are completely unconnected magnetically.

The reconnection that powers the bright points is driven by the convergence or divergence of the two opposite-polarity magnetic fragments and is likely to be of an impulsive bursty nature. This means that the reconnection will not continue in a steady manner but is likely to take place in frequent, but random, spurts that occur every few minutes. It is unclear whether the flaring stage of a bright point is just a very large sudden random release of energy or whether it is some completely separate event like the eruption of a mini filament.

In figure 1(*a*) an arrow indicates a three-looped bright point that resembles a bird in flight (figure 1(*b*)). The philosophy of the converging flux model was used to model this bright point by comparing it with images of the magnetogram below to discover the magnetic flux regions associated with this structure. These revealed an imbalance of flux with one positive and three negative fragments. The corresponding magnetic field topology of these four fragments was modelled as it evolved according to the observations through a series of equi-potential states. The newly reconnected field lines that formed are those shaded in figure 1(*c*) and compare very favorably with the structure of the bird bright point observed. Because of the imbalance of flux in this situation there would also have been newly reconnected open field lines that would not brighten since the heat flux along very extended loops would be small. They may, however, have enabled non-thermal radiation to be observed from particles accelerated along them.

Solar Coronal Mass Ejection: Observations

The Sun ejects matter into space. There appear to be two basic ejection classes, the first leading to the SOLAR WIND outflow, and the second leading to the occasional ejection of huge, discrete clouds known as coronal mass ejections (CMEs). First identified in the early 1970s, a typical CME can carry 1 000 000 000 t of plasma into space as part of the Sun's atmosphere erupts. The CME source regions within the Sun's atmosphere can be hundreds of thousands of km across and the resulting CMEs can expand into space at many hundreds of km s^{-1}. The rate of CME eruptions varies with the SOLAR CYCLE, but not by a large factor; one might expect about one CME event per day. CMEs represent a very significant disturbance to the solar wind. Given their size and mass, combined with the fact that the expanding clouds carry a frozen-in magnetic field, such events can engulf the Earth system and their arrival at the Earth can generate significant geomagnetic storms.

Observation of activity in the corona

In visible light the Sun's CORONA, or outer atmosphere, at its brightest, is a million times less intense than the solar disk. With such a huge contrast only rather special techniques can be used to observe the corona, effectively by removing the glaring solar disk emission. Indeed, one such technique is provided by nature.

During a total solar ECLIPSE the Moon occults perfectly the Sun's disk and the corona can be seen with the naked eye, as a system of milky, diffuse closed-loop features and streamers extending well into space. However, at best we see just a few minutes of totality and thus this only gives a brief glance. We may view the structure of the Sun's corona during the eclipse, but we cannot rely on such observations to observe the dynamic nature of the corona. Having said that, we can make use of an eclipse-like technique using an instrument called a CORONAGRAPH.

The bulk of our knowledge of CMEs comes from visible or 'white light' coronagraphs. Such a coronagraph is basically a telescope which contains an externally mounted or internally mounted device for occulting the solar disk. Obscuring such a bright, extended source does introduce difficulties with scattered light within the instrument; one can never produce as good an occulting disk as the Moon. However, modern coronagraphs can observe to within a tenth of a solar radius of the edge of the solar disk. In addition, because of scattered light from the Sun's disk in the Earth's atmosphere, one must operate such instruments at high altitude or from spacecraft, that is, above most of the atmosphere or outside the Earth's atmosphere.

Given the ability to produce an artificial eclipse one can monitor the Sun's atmosphere and study its structure and evolution at will, and this allows the study of activity in the Sun's corona, such as the CME eruptions.

The plasma in the solar corona is optically thin. This means that any observation along a line of sight is the integrated intensity of light emitted along that line of sight. Thus, we observe three-dimensional features projected onto a flat image—the plane of the sky.

The observation of CMEs is further complicated. The Sun's corona radiates in visible light because the light from the photosphere (the visible solar 'surface') is scattered off free electrons which are concentrated in the magnetic structures of the corona, and this is true for CMEs. The geometrical factors relating to the scattering process mean that coronagraphs are best suited to the observation of features over the limb or edge of the Sun. Thus, a CME ejected above the limb would, in general, appear to be brighter than one ejected out of the plane of the sky.

Another feature of the Sun's atmosphere allows further refinements to the coronal observing techniques. The Sun has a so-called K-corona and F-corona. The K-corona is the 'electron' corona; this is the true solar corona, i.e. radiation from the electrons contained within the structures in the Sun's atmosphere. The F-corona is effectively the near-Sun dust environment which is illuminated by solar radiation. For the analysis of the solar coronal structure and evolution, including CME activity, we wish to observe the K-corona. The K-corona is brighter than the F-corona close to the Sun, but, beyond about 2 solar radii, the F-coronal radiation begins to dominate. Thus, one has to separate the two and here we can make use of the fact that emission from the K-corona is heavily polarized. Indeed, this fact can help us to observe the coronal features against unpolarized scattered light such as in the Earth's atmosphere.

The first space-borne 'white light' coronagraph was flown in ORBITING SOLAR OBSERVATORY (OSO) 7 in 1973. With this device, the first CME observations were made, though it has been suggested that eclipse photographs from 1860 demonstrate that a CME was in progress, although no-one at the time could have identified it as an ejection. After OSO 7, extensive observations of CMEs were made using space-borne coronagraphs aboard SKYLAB (1973–4), P 78-1 (1979–85), SOLAR MAXIMUM MISSION (1980 and 1984–9) and SOHO, the Solar and Heliospheric Observatory (1995 to date). In addition, ground-based observations of CMEs have been made for many years with a similar device, called a K-coronameter, which measures the polarized brightness from the K-corona, at the HIGH ALTITUDE OBSERVATORY's Mauna Loa Solar Observatory in Hawaii.

The anatomy of a coronal mass ejection

The most basic definition of a CME is that it represents a discrete ejection of mass from the solar atmosphere detected as a transient feature expanding outward through a coronagraph field of view. CMEs represent a significant, rapid restructuring of a large portion of the solar atmosphere as the mass is ejected. CMEs occur in all shapes and sizes, and with many topological variations, but some basic characteristics are quite common. In this section we try to describe a 'typical' CME event, but draw attention to some features that vary from event to event.

First, to put the CME story in perspective we must remember that the solar atmosphere is an environment where the interplay between the solar plasmas and magnetic fields produces a complex hierarchy of magnetic loops containing plasmas at temperatures up to a few million kelvins. The loops are rooted in the body of the Sun and move with the surface plasma, which is subject to differential rotation as well as the turbulent effects of the convection patterns below the surface. The net result is an environment where magnetic field systems can be driven to a great deal of complexity; the motions of the solar surface literally weaving the magnetic field lines into highly stressed patterns. Eventually, one could imagine some kind of breakdown or rapid expansion of magnetic fields, where the response to further motion actually drives magnetic fields outwards and this becomes the CME, i.e. the ultimate result is the ejection of mass from the Sun. We know that SUNSPOTS, flares and other forms of solar activity are all driven by the Sun's magnetic fields and the CME is another form of solar magnetic activity. In short, one can state that it would be a logical process for the Sun to expel magnetic fields in the way described, and that is the CME. Having said that, the actual process by which the eruption occurs, the reasons for the topology we see and the prediction of mass ejections are all beyond our understanding at the moment.

The first view one might get of a CME is the expansion of a bright loop system rising into the solar corona from behind a coronagraph occulting disk. This can appear as a sharply defined single loop or a highly structured loop system. As the loop system expands outward one often sees a cavity in the region behind the loop, that is, the loop system is leading a region of depleted density. Within the cavity, for many CME events, one might find the ascending features of a prominence or filament which erupts as part of the CME event.

An example is shown in figure 1, taken using the coronagraph aboard the Solar Maximum Mission. This CME occurred on 14 April 1980 and it is shown here in a sequence of four images shown in negative form. The images were taken at 04:48, 05:44, 06:10 and 07:09 UNIVERSAL TIME (top left to bottom right) and in each image one can see streamers extending from the disk to the top and left of the image. These persist throughout the ejection event. In the images the Sun is tilted at 45°, with the north pole to the upper left, and the occulting disk (white in the negative) is 3 solar radii across.

The first image (top left) shows the CME loop just ascending above the occulting disc, apparently over the northern polar region. In the second image (top right), 56 min later, the CME loop has ascended further, to half way to the top left corner of the image, and a second loop can be seen. The second loop is an ascending prominence and it actually lies in a density 'cavity' which occupies the volume behind the outer loop. The third image (bottom left), taken only 26 min later, shows significant outward expansion, and, in the last image (bottom right), the CME outer loop has left the field of view and the prominence can just be made out.

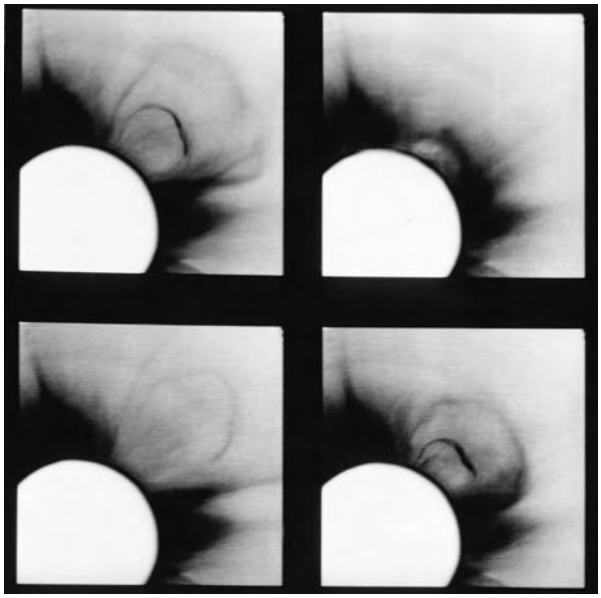

Figure 1. Four images of the CME of 14 April 1980 detected by the Solar Maximum Mission coronagraph (courtesy of High Altitude Observatory).

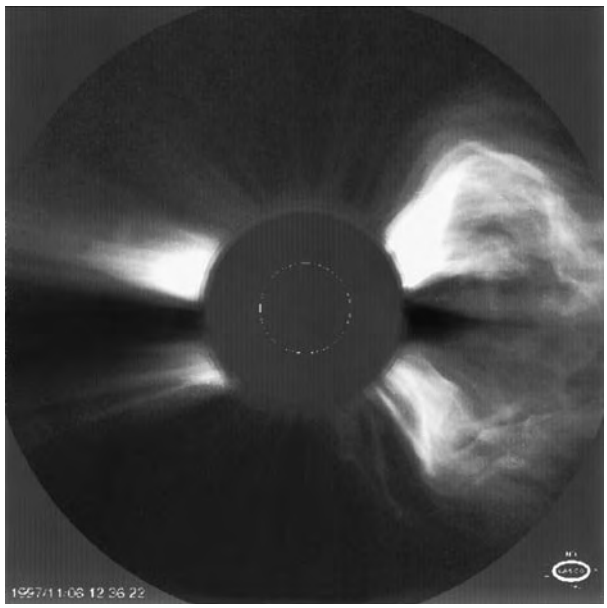

Figure 2. The CME of 6 November 1997 detected by the coronagraph on the Solar and Heliospheric Observatory (courtesy of Naval Research Laboratory).

A second CME event is shown in figure 2, this time taken by the Solar and Heliospheric Observatory coronagraph on 6 November 1997. This event shows a more complex outer loop system expanding out from the Sun, and no clear sign of a following prominence. In

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

this event the legs of the CME are particularly bright and the outer portions show a dramatic amount of hair-like structure. In this case, the occulting disk is also 3 solar radii across, and the solar disk is denoted by the white circle.

Typically a CME spans some 45 heliographic degrees of the solar disc, with clear legs which remain fixed over the same location of the Sun as the CME expands outward. However, CMEs have been reported with widths of less than 10°, and CMEs which are apparently directed toward or away from the Earth can appear to expand like a halo around the entire solar disk. Thus, although the average CME span is about 45°, and about 60% of CMEs have spans between 30° and 60°, CMEs of almost all spans are found.

Measurements of the speed of the outer loops of CMEs give typical outward speeds of 300–400 km s^{-1}, although CMEs have been detected with speeds as high as 2000 km s^{-1} and as low as just a few tens of km s^{-1}. The majority of CMEs show a modest acceleration with altitude from the solar surface, or a constant velocity. Very few display deceleration with height. The ascending prominence or filament material always follows the outer loops at a slower velocity. Since the escape velocity at the surface of the Sun is over 600 km s^{-1} the ejection process, at least in most cases, cannot involve the ballistic flight of a cloud which is launched by an impulse at a single point in time. The constant velocity or modest acceleration properties of CMEs, combined with the fact that they leave the Sun and can travel out as slowly as a few tens of km s^{-1}, suggest that the ejection expands outwards under the influence of a continuous process.

Statistical analyses indicate that 75% of CMEs contain prominence or filamentary material as part of the ejection. Figures 1 and 2 show an example of a CME with and without a prominence eruption. The prominence or filament can sit symmetrically within the CME loops (as with figure 1) or can appear to lie asymmetrically within the CME. The prominence can rise as a single entity within the CME but many events show partial prominence eruption under the CME.

The scattering process which allows the observation of CMEs also allows us to estimate the amount of mass contained in the CME, by measuring the intensity of the CME material, and many estimates have put typical CME masses at about 10^{12}–10^{13} kg, i.e. 1 000 000 000–10 000 000 000 t, although once again there must be a huge spread of masses.

Many CMEs occur underneath or within pre-existing coronal helmet streamers (see CORONAL STREAMERS). For a period which may last for some days the streamer can show signs of the impending ejection by displaying a gradual 'swelling'. The ejection itself can disrupt the streamer which may form again afterwards, although in the aftermath of a CME, for some days, the coronal region from which the CME erupted can appear to be swept out. Whether or not the CME 'cloud' is magnetically connected to the ejection site for some days after the ejection itself is open to debate.

We know that prominences can erupt as part of the CME process, but other forms of solar activity may accompany the event. For example, many CMEs involve SOLAR ACTIVE REGIONS; either the CME can appear to erupt from an active region or an active region lies at one footpoint of the CME event. For such active region related CMEs the ejection process can be associated with flare activity. However, detailed studies of the relative timing of flare onsets and CME onsets show quite clearly that the flare onset can occur well before, coincident with or after the CME onset. The only thing which is clear is that there is an association. The location of a CME associated flare can be anywhere under or near the span of the CME, and frequently in one leg. From these associations it is clear that CMEs and flares do not cause one another, but they often occur in close association.

Here, we have described a 'typical' CME. However, some CME events do not fit nicely into the scenario described. Some events are more 'tongue-like', appearing as an ascending mound. Some are more spikey and narrow. A newly discovered class of events are relatively common, small ejecta which appear to ascend within the streamer systems and their relationship to their larger brothers is not at all clear at this stage. Thus, while describing CME activity it should be noted that there may actually be different event types relating to different ejection processes, or there may be a wide event 'spectrum' with huge eruptions at one extreme, and small ascending clouds at the other extreme. Of course, all of this is subject to the sensitivity of our coronagraphs and as we develop better techniques we are likely to identify events or event types which were not previously visible.

Finally, one feature which we have not addressed here is the fact that the CME is a projection of a three-dimensional object projected onto a flat image, in the plane of the sky. This provides a few very basic questions. Is the CME loop representing the projection of a bubble, a loop or an arcade? If the CME loop was identified as the blast or coronal response to a sudden impulsive event from below, such as a flare, then a bubble-like expansion may be expected. However, no such cause can be identified. This, combined with the fact that the CME appears to be a signal of the eruption of a magnetic loop system, suggests quite strongly that we are witnessing the eruption of a magnetic loop or (more likely) arcade. The latter would fit nicely with the multiloop structures often seen in CMEs and is consistent with the idea that prominences lie within arcade systems in the solar atmosphere. It should also be noted that observations of prominences on the limb, particularly in eclipse images, reveal that the prominence arcade systems appear to enclose density depletions or cavities, which is also consistent with the basic structure of many CMEs.

Coronal mass ejections and the solar cycle

Solar activity adheres to an 11 yr magnetic cycle and CMEs are no exception to this. The rate of CMEs varies in harmony with the numbers of sunspots and rates of

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

flares. However, whereas the sunspot number increases by a factor of over 100 between the minimum and maximum of solar activity the number of CMEs appears to vary by a factor of only 10 or so, from about 0.1 per day to over 1 per day at solar maximum.

As well as variations in the CME rate, the solar cycle sees a variation in the latitude of CME source regions. During solar minimum CMEs tend to come from regions focused at or near the solar equator. At solar maximum, CMEs come from a larger spread of solar latitudes. This appears to be a direct association with other coronal features. At solar minimum the helmet streamers are mainly confined to a single belt around the Sun which lies at low latitudes. At solar maximum the corona is far more complex with systems of streamers at all but the highest latitudes. This appears to confirm that the majority of CMEs are associated with streamers.

The two CMEs shown in figures 1 and 2 show two extremes. Figure 1 shows a CME at the maximum of solar activity. Its apparent ejection over the polar region is most likely a projection effect. However, the ascending prominence was seen to erupt on the disk and it was formerly a high-latitude polar crown filament. On the other hand, figure 2 is a CME at solar minimum which erupted through a pre-existing equatorial helmet streamer.

The CME onset question

CMEs are detected using coronagraphs. Thus, the source regions of CMEs are obscured by the occulting disks of the very instruments which detect them. CMEs are seen clearly to rise up from behind the occulting disks of Skylab, Solar Maximum Mission and the intermediate coronagraph of the Solar and Heliospheric Observatory—i.e. they rise up from below half a solar radius above the limb of the Sun. Coronagraphs which are able to observe nearer to the disk, such as the Mauna Loa coronameter and the inner coronagraph of the Solar and Heliospheric Observatory, may be able to view portions of the CME source regions, although the observations thus far are inconclusive. To observe the onset of CMEs one must observe the lowest levels of the solar atmosphere and for this many researchers employ different techniques.

For reasons given above, coronagraphs are best suited to observations in the plane of the sky, that is, they are best suited to detecting CMEs which erupt over the edges of the Sun. Thus, even if one could observe the source region of the CME it would be near or even beyond the limb, or edge, of the Sun. Even if the source region of the CME is on the near side of the Sun, it will be near the limb and thus, because of the curvature of the Sun's disk, the features in the Sun's atmosphere associated with the CME onset will be foreshortened.

Before considering activity which we might observe on the solar disk which could be associated with a CME onset, we can make some comments on the CME source region. The average CME is 45° in span; some are much larger. CMEs often have well-defined legs which must indicate where they are rooted at the Sun, and those legs do not move during the eruption. These observations imply that the CME comes typically from a rather large source region, much larger than a flare or even an active region.

Flares and prominence eruptions are the most obvious forms of solar activity whose relationship with CMEs can be investigated. They are both observed using ground-based techniques. In basic terms, we can identify a CME using a coronagraph and then examine the underlying portion of the Sun to look for flare or prominence activity. Some discussion about the flare–CME and prominence–CME relationship are given above, but here we consider their possible role in the onset.

We already know that SOLAR PROMINENCES can erupt as part of the CME process, but is that the result of some kind of secondary process or could the prominence signal the driving force behind the entire CME event? Over the years the fact that the observing techniques used to detect CMEs and to observe prominence eruptions are so different has spawned many lines of research which consider each in isolation from the other. This has hindered our understanding of the full picture. However, whereas CMEs can be seen without obvious prominence material within them, coronagraphs never detect prominences ascending through the corona without an associated CME. Thus, the current thinking is that the prominence eruption is part of the CME process, but it does not drive the overlying CME loops.

As described above, the association between flares and CMEs is not straightforward. The association was recognized in the early years of CME observation. Again, flares could be identified from ground-based observations and their locations and timings noted with respect to any overlying CME activity (see SOLAR FLARE OBSERVATIONS). Quite logically, many researchers at that time suggested that the CME was some kind of blast or coronal response to an underlying flare. However, many CMEs occur without underlying flares and the timing and location of flares which are associated with CMEs imply that flares do not drive CMEs.

One has to conclude that the associated flare and prominence activity occur as a result of processes which also led to the mass ejection, but that neither the flare nor the prominence eruption cause the CME. For the same reasons, the CME cannot generate the flare.

So, far from making the picture clear, the examination of flare and prominence associations with CME onsets reveals a rather confusing picture.

The Sun's corona radiates ultraviolet and x-ray light. This is due to the fact that the plasma in the corona is so hot—rising from 6000 K at the photosphere to a few million K. However, as well as thermal emission, ultraviolet observations in particular reveal patterns—so-called emission lines—which come from trace elements in the Sun's atmosphere, such as iron, silicon, oxygen, magnesium and so on. We are aware of this because the wavelength or color of the emission characteristics is known from laboratory measurements. By making observations in specific emission lines one can view

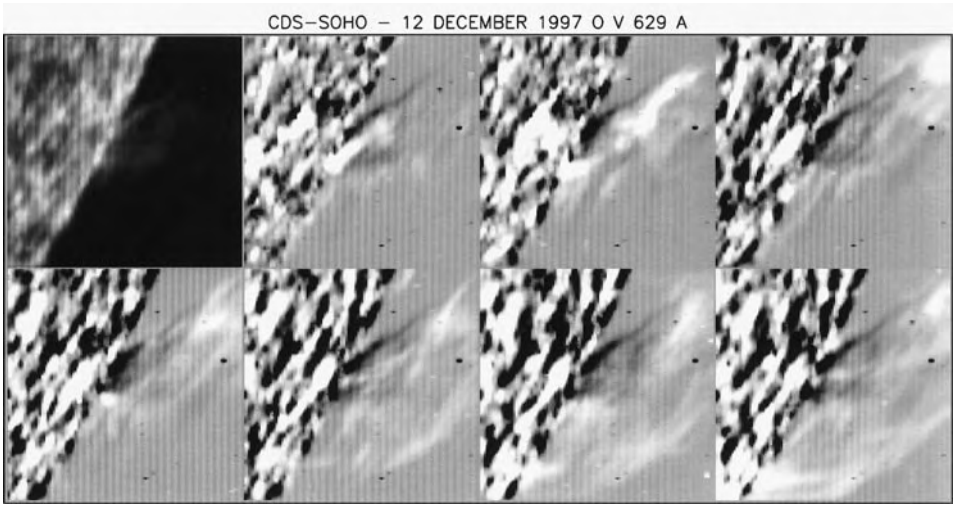

Figure 3. An ejection event detected in ultraviolet light from oxygen showing ascending plasma at a temperature of 250 000 K (courtesy of Rutherford Appleton Laboratory).

different temperature layers in the Sun's atmosphere and derive plasma characteristics of the solar plasmas, such as density, temperature, flow velocities and plasma constituents.

Employing these spectroscopic techniques, recent spacecraft campaigns, involving the Solar and Heliospheric Observatory in particular, have been used to examine in detail the solar atmosphere at the time of a CME onset. By making spectroscopic observations near the solar limb and awaiting an ejection a new view of the ejection process is being formed.

Figure 3 is an example of the fruits of one of these observing sequences, where, in this case, an ultraviolet spectrometer has been used to scan a region of the solar limb where an ejection is underway. Each image covers the same 200 000 km × 200 000 km area on the edge of the Sun at 16 min intervals from top left to bottom right. Although the event was detected in emission lines which allow the analysis of plasmas at 20 000 K–2 000 000 K, we show here radiation from a form of ionized oxygen which has a characteristic temperature of 250 000 K. The first image is a raw image which shows the solar limb and a weak, diffuse cloud extending into the corona. The subsequent images are differenced, i.e. the intensity of the first image is subtracted from each. Thus, for each image, white indicates an increase in intensity with time, and black shows a depletion with time. The heavy black and white mottled patterns of the solar surface reflect the activity of the supergranulation. However, the dramatic feature is the clear outward expansion of a 250 000 K cloud as part of a CME onset. The ultraviolet spectroscopy reveals clear ejection of material associated with a prominence eruption, as well as the outward expansion of plasmas up to several hundred thousand kelvins. Hotter plasmas (around 1 million kelvins and upwards) show little evidence for the ejection at all, and certainly confirm that there was no hot, impulsive event at the onset. These spectral analyses are continuing and, at this time, we conclude that the ejection process is a very subtle event, i.e. the events which are so dramatic in the high corona are really rather insignificant lower in the atmosphere.

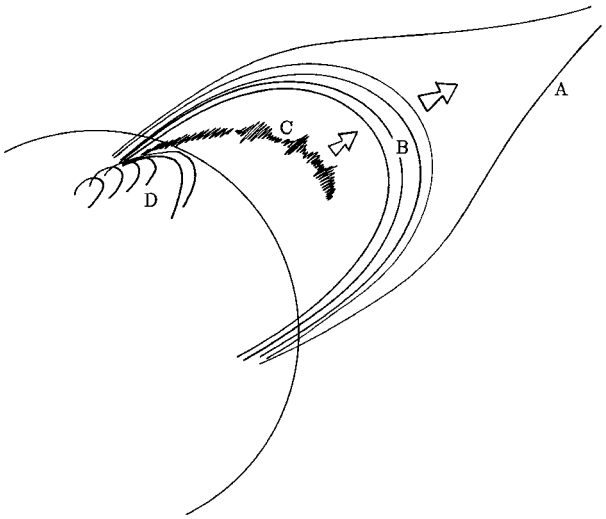

Figure 4. A schematic model of the CME process indicating (A) a pre-existing coronal streamer, (B) the ascending CME loops, (C) an erupting prominence and (D) an underlying active region.

Conclusion

Figure 4 shows a schematic of the CME process as many would describe it today. The salient components of the cartoon are (A) a pre-existing coronal streamer, (B) the ascending CME loop structure, (C) a prominence erupting behind the CME loops and (D) an active region.

Dirac House, Temple Back, Bristol, BS1 6BE, UK

In this case, we include the pre-existing streamer (A) although for some events such a feature may not be apparent. Under the streamer are closed-loop systems spanning some tens of heliographic degrees; this is a typical streamer form and size. These loops may be rooted in quiet Sun regions but in this case we show an active region (D). Under one portion of the loop systems within the span of the streamer is a magnetic arcade containing a filament or prominence.

The magnetic fields are rooted in the body of the Sun. As a result of the differential motion of the solar 'surface' the loop footpoints may shear, i.e. slide in different directions with the flow of the Sun. Such motion can cause the loops to begin to rise as the magnetic system tries to achieve an equilibrium. This shear activity, combined with magnetic complexities associated with the associated active region, can cause the large-scale fields to achieve a non-equilibrium situation or a lack of stability. The loops may expand outward. As they begin to expand the streamer above shows signs of some swelling. The continued ascent of the loops heralds the ascent of the outer loop of the CME as we know it.

As the magnetic loops expand out, either the arcade enclosing the filament or prominence ascends with it or quite separately reaches a non-equilibrium because of the removal of the overlying magnetic fields which would have acted to anchor the system. Thus, the eruption of a prominence (C) follows the CME. The exact nature of the ascending prominence will depend on many factors such as the state of development of the prominence prior to the event.

In this picture part of the ascending loop system is rooted in an active region (D). One might expect that the effect of this opening of field lines could in itself drive secondary changes in the active region. This may result in the onset of a solar flare if the conditions are right. Such an event may occur at any time in the sequence and, thus, may occur before the CME, at the same time as the CME onset, or after the CME onset. Thus, the CME onset and the flare are associated but do not cause one another. They are both driven by the same basic process.

Solar Coronal Mass Ejection: Theory

Solar coronal mass ejections (CMEs) are episodic expulsions of mass out of the solar CORONA involving large-scale reconfigurations of the corona. In a typical event, several 10^{15-16} g of plasma pre-existing in the low corona is expelled into interplanetary space, with a rate of occurrence varying from one event every few days at activity minimum to as high as three events per day at activity maximum in the course of a SOLAR CYCLE. The CME and the FLARE are the two most energetic phenomena, liberating some 10^{31-32} erg of energy in each case, among the myriad of time-dependent phenomena in the corona. Since it involves length scales of the order of the solar radius and time scales characteristic of sound and Alfvén speeds in the corona, the CME is appropriately described by MAGNETOHYDRODYNAMICS (MHD) and is thus one of few known MHD processes in astrophysics which are accessible to direct imaging as a spatially resolved time-dependent event (see SOLAR CORONAL MASS EJECTION: OBSERVATIONS).

Discovered in the 1970s, CMEs have been a subject of intensive research, with several outstanding questions to which contending theoretical answers have been proposed. The rest of this article treats some of these questions: those dealing with the causes and consequences of CMEs, the origin of the CME energy, the nonlinear, time-dependent MHD flows of CMEs in the corona, and the characteristic structural form of the CMEs and their manifestations in the SOLAR WIND.

Causes and consequences of CMEs

The observed close association between CMEs and the other two major forms of coronal eruptions, namely flares and eruptive prominences, was the basis for the theory, once seriously considered, that CMEs are the responses of the corona to these other eruptions occurring lower down in the corona. This suggestion was attractive because of its physical simplicity. It was also in keeping with the reasonable idea prevalent before CMEs were discovered that the impulsive flare might produce a blast wave traveling out of the corona. This blast wave was identified with type II traveling radio noise and with shock wave structures observed in the solar wind by satellites at 1 AU. In this theory the CME would be identified with the blast wave generated by the flare. This scenario was pursued with many simulations with time-dependent MHD numerical codes treating CMEs as the results of impulsive inputs of flare-like energies at the base of static atmospheres embedding a potential magnetic field.

The flare initiation of CMEs as a theoretical idea was shown to be not tenable by the observational results of R Harrison and by the follow-up work of A Hundhausen. Although the question is still being debated by some theorists, it is widely accepted that where observation is of sufficiently good quality, when a CME is associated with an observed flare, the flare does not as a rule precede the CME onset. Actually, events were found which showed that the CME preceded the associated flare. This rules out the flare as a cause of CMEs. From the theoretical point of view, there are several other aspects of the CME phenomenon which suggest that flares are not likely to be the cause of CMEs, notable of which are the following two points. Firstly, an impulsive ejection of the corona would involve the highest speeds of the MHD medium whereas the observed CME speeds fall in a huge range, from 10 to 2000 km s^{-1}, with a median of about 400 km s^{-1}. Secondly, CMEs tend to show a characteristic three-part structure in white-light coronagraph observation—a bright loop leading a dark cavity containing a bright core. This structure is reasonably interpreted to be corresponding to that of the pre-existing helmet streamer—a bright dome overlying a dark cavity containing a quiescent prominence (see CORONAL STREAMERS). The breaking up of a coronal helmet has been commonly observed to be the origin of a CME. Thus the CME is a nonlinear but not necessarily an impulsive 'breaking loose' of a large-scale coronal structure which preserves the coherence of the three-part structure.

The rejection of a flare as the cause of the CME is an important theoretical development, for it brings about a new or different way of viewing the large-scale corona. This view has a strong theoretical appeal because it integrates various theoretical and observational results in terms of simple MHD principles.

The solar corona is ordered by an interplay between two competing effects as the result of heating and the presence of magnetic fields. The hitherto still poorly understood heating maintains the corona at temperatures of the order of 1 to 2 million degrees with such a degree of relentlessness that at no time is the corona in any large bulk part able to cool down significantly below these temperatures. One of the consequences of its high temperature is the high thermal conductivity of the corona. Combined with the inverse square fall-off in solar gravity, the hot corona can extend so far out from the solar surface that the natural state of the corona is one of outward expansion into the solar wind, as first pointed out by E N Parker. This expansion is not ballistic or forced from below. The expansion results from a failure of gravity to confine the upper atmosphere. The upper atmosphere continuously expands to supersonic speeds, during times of more or less steady conditions, while the lower atmosphere heaves continuously outward, departing only weakly from hydrostatic equilibrium, to make up for the expansion.

The presence of magnetic fields in the electrically highly conducting corona introduces the Lorentz force, whose action may be decomposed into that of a magnetic pressure force combined with that of a magnetic tension force. The magnetic pressure can only enhance the tendency of the corona to expand. The magnetic tension force provides a means of restraining the expansion provided it acts towards the Sun and provided the magnetic field is sufficiently intense. This occurs low in the corona where magnetic fields are bipolar with the magnetic feet anchored to the solar surface on the two sides

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

of a polarity inversion line. The low corona is dominated by the typically 10 G magnetic field, with a plasma β of the order of less than 0.1, that is, with the plasma pressure typically of the order of a tenth of the magnetic pressure. In such a region, the closed magnetic fields may trap a parcel of plasma in more or less static equilibrium against the global tendency to expand. This is the origin of the ubiquitous coronal helmet streamer straddling a photospheric magnetic inversion line. Outside of the helmet, the field is strong but, because it extends too far out where the solar wind dominates, it is kept open into interplanetary space by the solar wind.

Another way of seeing the effect of the magnetic tension force is to note that, under the condition of high electrical conductivity, a bipolar magnetic field anchored to the surface of the Sun has a tendency to remain closed because this is a state of minimum magnetic energy. The competition alluded to above is then between this magnetic tendency and the opposing expansion of the global corona. The balance between these competing effects determines how much mass and magnetic flux is trapped in a coronal helmet surrounded by open magnetic fields where the wind flows. The CMEs are then the consequence of the failure of this balance when the helmet would break loose to move out along with the global solar wind.

In this view, the term 'loss of equilibrium or non-equilibrium' is invoked to make the point that it is not just an instability. The remarkable aspect of a CME is that, when initiated, it expands out in a global nonlinear flow with a total mass of ejection characteristically of the order of a few times 10^{14-16} g. The idea of an instability merely implies that the system would evolve away from an initial equilibrium when perturbed, but such a behavior does not *a priori* require the ejection of a huge amount of material out of the corona, a basic feature of the CME phenomenon. It is the teetering between confinement and expansion of plasmas trapped in the coronal helmets to result in a global loss of equilibrium that underlies the CME phenomenon, in this theoretical interpretation. Depending on physical circumstances under which this loss of equilibrium develops, it is theoretically conceivable that the structure breaking up may maintain its internal form with coherence and may move out with a broad range of speeds as opposed to the case of an impulsive blast-off.

The coronal magnetic field that produces the CME is also the agent for producing the PROMINENCE and its eruption, and the solar flare. Thus it is not a simple causal relationship one needs to find among these major eruptions making up the activity in the corona. This is an important point for theory, and it is reflected in the facts that flares, as defined as a sudden localized heating of the corona, have several different varieties and that the rate of flare occurrence increases by orders of magnitude over a solar cycle as opposed to an increase of a factor not larger than 10 in the CME rate over the same period of time.

There is, however, a particular relationship between CMEs and flares of a special kind, often referred to as the two-ribbon flares, which is of theoretical significance. The adjective 'two-ribbon' came originally from observations of the Hα part of this type of flare, referring to the characteristic heating occurring at the chromosphere along two bands which separate in time. This type of flare, known long before the discovery of CMEs, has been well explained in terms of magnetic reconnection taking place above the flaring chromosphere which recloses a magnetic field that has been caused to open up. The two flare ribbons in the chromosphere are then reasonably interpreted to be marking the footpoints of newly reconnected fields containing heated plasma. As more magnetic fields reconnect, newly heated footpoints light up while footpoints heated earlier cool out of visibility to produce the effect of the separating ribbons. With soft x-ray observations available from space these days, the two-ribbon flares are observed as long duration outputs of soft x-rays (hours to a fraction of a day) rising above the full-disk output, or as arcades of flaring loops in soft x-ray images.

Before CMEs were known, this flare mechanism lacked a physical reason why the magnetic field should open up on its own to produce a two-ribbon flare. The idea that a CME is the opening up of the magnetic field in a coronal helmet provides the missing ingredient. If the two-ribbon flare is indeed the result of the reclosing of opened magnetic fields by reconnection, and the CME is indeed responsible for the opening up of an initially closed magnetic field, the CME necessarily has to precede the two-ribbon flare associated with it. Theoretically, the reconnection could begin as soon as the CME takes off with the field opening up, or the reconnection could be delayed until after the field has completely opened up and the CME is well on its way out of the upper corona. The latter is supported by some observations and the former leaves the temporal sequence ambiguous because the flare would have an onset very close to, or, in practical terms, almost simultaneously occurring with the CMEs. What this theory would not accommodate would be the observation of a two-ribbon flare preceding the associated CME. If it can be shown that such an event occurs and that the association between the flare and CME is not by chance, then the event cannot be explained by the theory, pointing to a much more complex physical behavior than the one envisioned in the theory.

CME energy

The mechanical energy of a CME is impressively large. The often quoted CME energy of 10^{31-32} erg is the sum of its kinetic energy and the work done against solar gravity to lift its mass of 10^{15-16} g out of the corona. The gravitational potential energy typically is about a half of the sum, as can be seen from the fact that the gravitational escape speed in the low corona is about 500 km s^{-1} whereas the observed median speed of CMEs is about 400 km s^{-1} with the large range mentioned above. The sound speed of the 2 million degree corona is about 120 km s^{-1}. The Alfvén speed in the low corona can be estimated to be in excess of

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

700 km s^{-1}. Therefore, a striking feature of the CME is that a great many CME speeds are supersonic, sub-Alfvénic, and below the low-coronal gravitational escape speed.

It is widely held that the CME energy originates from energy contained within the corona previously stored in the magnetic field. This view is based on noting that the CME moves at speeds near the limit or in excess of the characteristic MHD speeds of wave propagation in the corona. In this case, it is not possible for the CME to be driven by photospheric processes which involve typical speeds of 0.5 km s^{-1}. It is possible that the photosphere may stress the coronal magnetic field over a long period of time to result in a build up of energy in the corona, but it is not likely in this view that the photospheric motion, given its small magnitude, is relevant during the course of the CME moving out of the corona at the characteristic high speed of the latter. This point of view is supported by the fact that to date no surface photospheric motions of a particular type have been shown to be indicative of a CME leaving the solar corona directly above the photospheric region of observation.

A minority view has persisted, hinting at some possible large-scale non-MHD effects in which the CME is driven by currents generated at the photosphere or in the solar convection region. This view has remained speculative and non-quantitative.

Accounting for the CME energy in terms of magnetic energy stored in the corona has turned out to be a deeper problem than previously appreciated. Taking the simplifying limit of the corona as a perfect plasma conductor with negligible inertia, it was an attractive idea to try to account for the energy in the field-aligned currents of a FORCE-FREE MAGNETIC FIELD anchored to the surface of the Sun. These currents were taken to be induced by the stressing of the field by slow but persistent photospheric motion taking the embedded magnetic footpoints along with it. It was proposed in the 1970s that the spontaneous opening up of a closed force-free magnetic field may result from a build-up of magnetic energy by surface stressing to a level above that of an open state. This idea was shown to be incorrect by J J Aly in the 1980s, who proposed a now widely accepted conjecture that the build-up of energy in a closed and anchored force-free magnetic field cannot exceed the energy of any open magnetic field having the same anchored footpoints on the solar surface.

The energy demand of a CME is especially impressive if one has to account not only for its energy but also for the energy of the open field it leaves behind, in the light of Aly's conjecture. The large amount of energy in the open field left behind by the CME would neatly account for the post-CME flare that results from the reclosing of the opened magnetic field. Therefore, the theoretical question on the energy storage for the CME is one of demonstrating that there could be coronal structures with closed magnetic fields in possession of two huge amounts of free energy, that carried away in the gravitational and kinetic energy of the CME and that left behind in the open magnetic field to fuel the CME-associated flare. This, by Aly's conjecture, cannot be accounted for by the stressing of force-free magnetic fields.

A first step in the resolution of this problem is to realize that the force-free assumption is not valid over the large scale of the corona. In the thermally highly conducting corona, pressure is almost isothermal and it falls with height less rapidly than the magnetic pressure, especially with gravity dropping inversely with distance squared. Both the pressure and the solar wind dominate over the magnetic field at increasing distance from the Sun and the force-free assumption is invalid over such scales, for example, as characterized by the radial extent of the helmet streamer. Over these scales, the Lorentz force is not zero everywhere but interacts with pressure gradient and gravitational forces, and all these forces also produce the solar wind in the open-field regions.

Once this is recognized, models of the corona in static equilibrium can be constructed to show that the necessary amount of magnetic energy can be stored to fuel ejection of a CME and its associated flare. Of particular note is that the magnetic energy is most efficiently stored if a part of the magnetic field is not in the form of simple bipolar anchored field but is in the form of a flux rope detached in its main part from the coronal base, that can be identified with the cavity under the helmet-streamer. The confinement of this flux rope in equilibrium requires the weight of the large mass in the helmet dome. In this model, the large mass of the CME plays the very role of trapping the magnetic energy in the pre-eruption stage that eventually drives the CME.

This promising resolution of the energy problem has also raised a new question. If the magnetic energy needed to drive the CME requires interaction between the plasma and the field for its storage, it must follow that plasma pressure forces must also play a significant role in the CME outflow. This implication is not surprising when it is realized that the Lorentz force cannot work against gravity in the direction of the magnetic field, only the component of the pressure force in that direction can. And, working against gravity is an essential aspect in the energetics of the CME. Ultimately, to understand the effect of pressure would require an understanding of the nature of coronal heating under the time-dependent circumstance of the moving CME.

The time-dependent MHD flow of a CME

The simplest description of the CME in fully developed motion uses the one-fluid MHD equations including the presence of solar gravity. To avoid the complication of the energy and heating of the plasma, a polytropic assumption with an index taken smaller than 5/3 is usually made to simulate the heating of the coronal, largely proton, gas in expansive motion.

The only general approach to treat the MHD equations is by the use of numerical codes with the capability of dealing with at least two dimensions in space. Previous work had treated the flare-initiated CME theory and the shearing of magnetic footpoints to force

a spontaneous opening up of the coronal magnetic field. These works had been instructive in their respective ways but have not dealt with the CME nonlinear flows such as observed in the low corona. Recent numerical modeling efforts have begun to address the idea that the CME cavity is a magnetic flux rope and morphological agreement between two-dimensional models and the observed three-part structures of CMEs have been obtained, lending credence to the suggestion of magnetic flux ropes playing a role in the CME phenomenon.

The MHD equations for a polytrope of index 4/3 admit a family of self-similar solutions both in two- and in three-dimensional space. These solutions have been useful in capturing the essence of the MHD time-dependent expulsion of mass out of a gravitational potential well. Among the properties directly demonstrated with these solutions is that the transport of magnetic field, mass and the 4/3 polytropic pressure may proceed in a mode such that gravity can be countered throughout the expulsion process. The result is that the modeled CME could in this mode of behavior travel out of the corona with mildly accelerated or constant speeds in an enormous range of speeds, such as seen in the observed CMEs. The possibility of generating solutions in this class with fully three-dimensional variations was also exploited to produce a CME geometrically sophisticated enough for direct (favorable) comparison with white-light observations.

The large range of observed CME speeds implies that a rich variety of MHD shocks may be associated with this highly nonlinear flow. The fast MHD shock has behaviors which are intuitively simple modifications of the hydrodynamic shock by the presence of magnetic fields. The slow and intermediate MHD shocks have properties which can be counter-intuitive, such as the possibility of having a shock surface shaped with a concavity away from the shock driver. The leading fronts of observed CMEs have shown a variety of shapes suggestive of such unconventional shock-surface geometry. Recent time-dependent MHD models have demonstrated that these observations may be explained in terms of the MHD shocks formed by the CMEs plowing into the ambient corona at speeds in the supersonic but sub-Alfvénic range. Much work remains to be done in this classical area of MHD shock theory, especially in the discovery of the role of the intermediate shock in the CME outflow.

In interplanetary space, the signatures for recognizing a CME in the solar wind are being developed. Among these signatures are the bidirectional streaming electrons indicative of magnetic lines of forces with both ends anchored to the low corona such as might be expected from the stretching out of bipolar lines of force by the CMEs. The three-part structure of the CMEs seen in the corona has not been unambiguously identified with their counterparts in interplanetary space but some promising results have been obtained, including the identification of the CME cavity with the so-called interplanetary magnetic clouds. Both the cavity and the magnetic cloud may be the manifestation of a magnetic flux rope. It is conceivable that the CME will undergo significant evolution as it travels along with the solar wind. Much theoretical work and modeling remain to be done in parallel with observational studies of coronal and interplanetary observations to address these issues.

Conclusion

The discovery of CMEs in the 1970s has ushered in a new chapter for coronal physics, taking us from the concern with the solar wind structures in the synoptic regime to the time dependence of episodic mass expulsions, and taking us from the preoccupation with flares to a new form of eruption involving just as much energy. Worthy of note is the fact that the flare is dissipative in nature, heating of the coronal plasma; whereas, the CME involves liberation of energy in the ordered forms, gravitational potential and kinetic motion. The two forms of eruption are related in ways that are not simple and the physics of the corona is richer than many would have realized when CMEs were first discovered. Much remains to be done, and there is a confusion of ideas. These have been partially resolved and the view will probably continue to evolve.

Solar Cycle

The term *solar cycle* refers to a quasi-periodic variation with a period of about 11 years, visible in many of the Sun's observables. The solar cycle is most easily observed in indices directly related to the Sun's magnetic field, such as SUNSPOTS. During the last decades, solar-cycle variations have also been found in many other aspects of the Sun (irradiance, surface flows, coronal shape, oscillation frequencies, etc). The modulation amplitudes may vary widely between different indices. It is minute in visible light, and this explains why the solar cycle is not visible to a casual naked-eye observer. Elsewhere (in the far ultraviolet, x-rays, radio frequencies) the modulation amplitude is large (table 1). The prime cause of the solar cycle is a quasi-periodic oscillation of the SOLAR MAGNETIC FIELD.

Magnetic-field indices

The oldest and best known index of the solar cycle is provided by sunspots, whose discovery for Europe around 1610 is associated with the names of FABRICIUS, GALILEO and SCHEINER. The commonest sunspot index is the Zürich sunspot number $R = K(10g + f)$, where g is the number of sunspot groups, f is the number of individual spots and K is a coefficient that corrects for differences in the quality of the observations. Usually one derives an annual average $\overline{R}$, shown in figure 1. The most striking feature of the sunspot record is the Schwabe cycle of about 11 years, discovered by Samuel Heinrich SCHWABE in 1843. By convention, the cycle that began in 1755 is assigned number 1; hence cycle 23 began in 1997.

Cycle shape

A typical sunspot cycle in figure 1 is characterized by a sharp rise from minimum to maximum, lasting 3–6 years (on average 4.8). The duration of the rise phase is anticorrelated with the height of the maximum (Waldmeier's rule). The maximum is followed by a gradual decline lasting 5–8 years (on average 6.2). Whereas the maxima of the Zürich number are typically well-defined, this is not the case for some other SOLAR ACTIVITY INDICES. For example, it has been suggested that the number of *large* sunspots has a double-peaked maximum.

Most indices vary roughly in phase with the sunspot number, and therefore the sunspot extrema are also referred to as the solar minimum and the solar maximum. On the other hand, some coronal indices are clearly out of phase with the sunspot cycle, and they peak at the sunspot minimum (see below).

Table 1. Selected indices of the solar cycle.

	Period	Minimum†	Maximum	Unit
Magnetic indices				
Zürich annual mean sunspot number $\overline{R}$	1610–1997	0–11	38–201‡	
Weak field (B < 25 G) flux	1975–92	15–20	30–33	10^{22} Mx
Strong field (B > 25 G) flux	1975–92	2–3	60–80	10^{22} Mx
Full-disk spectral indices				
10.7 cm radio flux	1947–95	70	160–280	10^{-22} W m^{-2} Hz^{-1}
393.4 nm Ca II K 1 Å index (UV)	1975–90	0.085	0.105	
121.6 nm Lα UV flux (SME§)	1982–9	2.5	4	10^{11} photons cm^{-2} s^{-1}
0.1–0.8 nm x-ray flux (GOES‖)	1974–88	<0.01	3	10^{-6} W m^{-2}
Other indices				
Total irradiance (ACRIM¶)	1979–97	1365.6+	1366.9+	W m^{-2}
530.3 nm green coronal index	1939–94	2	10–20	10^{16} W sr^{-1}
Solar wind speed at 1 AU (NSSDC*)[1]	1965–87	400	500–530	km s^{-1}

†Minimum occurs at solar minimum, except for solar wind speed, whose minimum occurs at solar maximum.

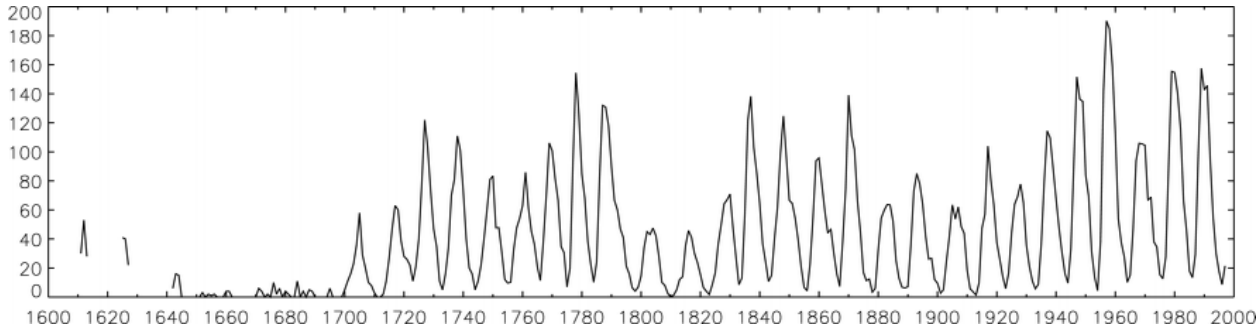

Figure 1. The Zürich annual-mean sunspot number (data from the Geophysical Data Center, Boulder, CO, USA).

Cycle length and amplitude

Individual sunspot cycles since 1710 lasted between 7 and 14 years (on average 11) and had amplitudes in the range $38 \leq \overline{R} \leq 201$ (on average 105). No significant correlation between length and amplitude of individual cycles has been found. For nearly all of the cycles 0–21, the amplitude of an odd-numbered cycle exceeds that of the preceding even-numbered cycle (the Gnevyshev–Ohl rule).

Magnetic bipoles

Sunspots are sites of strong magnetic fields ($B \approx 2$–3 kG). Frequently, they form bipolar pairs, consisting of a leading spot and a trailing spot with respect to the solar rotation. Virtually all bipolar pairs obey the Hale–Nicholson polarity rules. (a) The magnetic polarities of leading and trailing spots are opposite, and those of the leading spots in one hemisphere are opposite to those of the leading spots in the other hemisphere. (b) The predominant sunspot polarities reverse after the solar minimum. Taking into account this polarity reversal, the magnetic field has a period of about 22 years, which is referred to as the Hale cycle.

The axes of bipolar pairs are slightly tilted with respect to the equator, leading spots being closest to the equator (Joy's rule). Tilt angles (on average 4º) increase with latitude, but show no significant variation with the solar cycle. Also the relative size distribution of SOLAR ACTIVE REGIONS is almost invariant throughout the cycle. The only exception is a period of 2–3 years before solar minimum, during which small bipolar regions are relatively more frequent. This is due mainly to the emergence of opposite-polarity ephemeral regions at high latitudes. They follow the Hale cycle with a minimum preceding the solar minimum by about 1 year.

Butterfly diagram

The latitudinal distribution of sunspots as a function of time can be viewed from the butterfly diagram (figure 3). Sunspots, indicated by black dots, appear in two belts parallel to the equator, whose midpoints migrate equatorward from about ±27º to about ±8º during the course of a cycle (Spörer's law), and whose widths attain a maximum of about 36º during the sunspot maximum. The polarities of the northern and southern wings of the butterfly diagram are opposite, and they alternate from one Schwabe cycle to the next. Sunspots exist for at most a few months, and they hardly migrate themselves, but in the course of a cycle every new sunspot appears on average at a lower latitude.

Sunspots and active regions have a tendency to emerge near existing active regions. These loci of flux emergence, referred to as active nests or active longitudes, may live up to 6 months (see SOLAR ACTIVITY COMPLEXES). The magnetic field of sunspots probably has its origin near the base of the SOLAR INTERIOR CONVECTION ZONE, at a depth of about 200 000 km, and the butterfly diagram traces this deep-rooted, large-scale magnetic field.

Magnetic network

Magnetograms (figure 2) reveal an extended pattern of surface fields, referred to as the magnetic network (see SOLAR PHOTOSPHERE: INTRANETWORK AND TURBULENT MAGNETIC FIELDS). Around the solar maximum, the magnetic network up to a latitude of about ±60º consists mainly of large unipolar regions, in which the bipolar active regions are embedded. For about 5 years around the solar minimum, the network is much weaker and has mainly mixed polarities. From the magnetograms it is also concluded that the solar-cycle modulation decreases with decreasing field strength (table 1). Thus the total unsigned flux of strong-field regions ($B > 25$ G) varies by a factor 30–40, compared with a factor of only 1.5–2 for weak-field regions ($B < 25$ G).

Polar field

The weak polar magnetic field has mainly one polarity at each pole, and the two poles have opposite polarities. Between the solar minimum and the solar maximum, its polarity on each hemisphere agrees with that of the leading spots of bipolar pairs. Around the solar maximum, the polar field changes its sign.

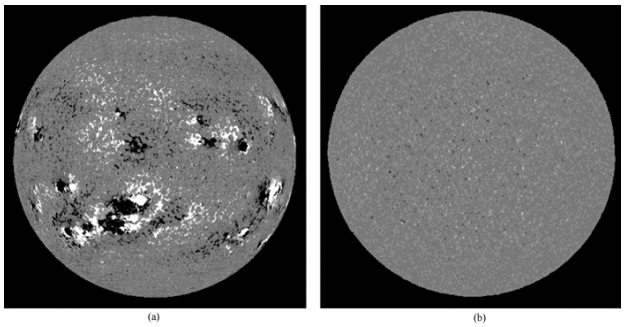

Figure 2. Magnetograms of the solar disk taken respectively at 23 August 1990, near the solar maximum, and at 15 October 1996, near the solar minimum. Black and white indicate magnetic regions of, respectively, negative and positive polarity (National Solar Observatory, USA.)

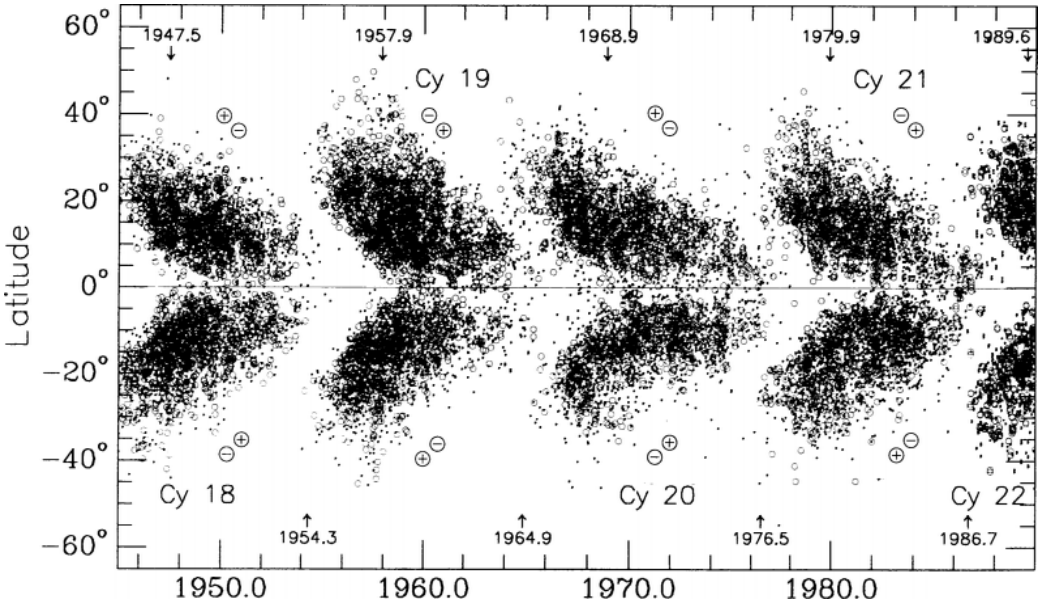

Figure 3. Butterfly diagram. Arrows denote sunspot maxima (top) and minima (bottom); ● and ○ indicate sunspot regions smaller and larger than 80×10^{-6} of a hemisphere, respectively; ⊕ and ⊖ indicate whether the magnetic field of leading and trailing spots is directed outward or inward, respectively. (Adapted from K L Harvey (1992).)

Other periods besides the Hale cycle

If the Sun's surface field as a function of time is decomposed in terms of spherical harmonics, one finds very different frequency spectra for axisymmetric modes (i.e. $m = 0$) with odd ℓ (i.e. antisymmetric with respect to the equator) and axisymmetric modes with even ℓ. Whereas odd-ℓ modes are dominated by the Hale cycle, even-ℓ modes are weaker and have no single, well-defined frequency. No such difference between even- and odd-ℓ modes is observed for non-axisymmetric modes ($m \neq 0$), which have a main peak at the Hale cycle, and smaller peaks at its higher harmonics, almost irrespective of ℓ. Altogether, though, the reality of magnetic cycles shorter than the Hale cycle is still uncertain.

Magnetic cycles longer than the Hale cycle have also been proposed. The sunspot record appears to be modulated by a period of 80–90 years, referred to as the Gleissberg cycle, but the number of oscillations is very small (about three can be seen in figure 1). There is some evidence for this and longer periodicities in the records of ^{14}C and ^{10}Be, but their existence remains uncertain (see SOLAR ACTIVITY: LONG-TERM RECORDS).

Grand minima

During the so-called Maunder minimum (1645–1715) sunspots were very few and, prior to 1700, no cycles are apparent. Coverage of the sunspot record in this period is estimated to be about two-thirds, and the reality of the Maunder minimum is undisputed. This and earlier grand minima such as the Spörer minimum (1420–1530) are clearly visible in the ^{14}C and ^{10}Be data. Timing and duration of the known grand minima are irregular, but the Sun may have spent as much as a third of its time in grand minima. Surprisingly, these records also suggest that the solar cycle continued throughout the Maunder minimum at a reduced level, an issue which is of particular interest for solar dynamo theory (see DYNAMOS: SOLAR AND STELLAR). More recent but less impressive prolonged minima, visible in figure 1, are the Dalton minimum (1800–30) and the Modern minimum (1880–1910).

Dirac House, Temple Back, Bristol, BS1 6BE, UK

Grand minima are but the most conspicuous manifestations of solar variability, which is also apparent for example in length and amplitude variations of the sunspot cycle. The question of whether solar variability should be ascribed to (quasi-) periodic or chaotic nonlinear behavior on the one hand, or to stochastic processes on the other hand remains as yet unresolved due to the lack of a sufficiently long dataset (see DYNAMO THEORY).

North–south asymmetry

Asymmetry between sunspot activity in the northern and southern hemispheres is larger than average during solar minima and was particularly strong during the Maunder minimum, when the few observed sunspots seem to have been concentrated on the southern hemisphere. Smaller but nevertheless clear north–south asymmetries can be seen in the regular sunspot cycle as well, for example during the years 1955–65 (figure 3).

Irradiance and spectral properties

Solar-cycle modulations are apparent throughout most of the Sun's electromagnetic spectrum, which extends from radio to gamma ray energies (see SOLAR ACTIVITY INDICES). Only in the far infrared, a technically difficult spectral range, has no modulation been demonstrated yet. Data for a selection of full-disk spectral indices are included in table 1. They exhibit a wide range of minimum-to-maximum variations, from 0.1% for total SOLAR IRRADIANCE up to factors >100 for the x-ray flux at 0.1–0.8 nm. As a general rule, the larger the solar-cycle modulation of an index is, the more it is dominated by phenomena related to strong magnetic fields.

Solar irradiance, like most spectral indices, is largest at the solar maximum, in spite of the darkening by sunspots. This net luminosity increase is attributed largely to an overcompensation by photospheric faculae, the number of which peaks at solar maximum (see SOLAR PHOTOSPHERE: FACULAE).

Solar oscillations and internal structure

The frequencies of solar p-mode oscillations increase by up to 0.1% from solar minimum to solar maximum (see HELIOSEISMOLOGY). The shift increases with frequency, and is largest for oscillations with a period of about 4 min. Such a frequency dependence is interpreted as evidence that the shifts are caused by magnetic fields near the solar surface, rather than by a deep-rooted field. At the solar minimum, p-mode amplitudes are about 35% larger than at the solar maximum.

The rotational splittings of p-mode frequencies also depend on solar-cycle phase. They are possibly related to solar-cycle variations in the Sun's internal rotation, but attempts to derive angular-velocity changes from the measured frequency splittings have so far yielded inconclusive results.

A solar-cycle modulation of the neutrino flux originating in the Sun's core is unproven, and seems unlikely on theoretical grounds (see NEUTRINOS). No significant solar-cycle modulation of the solar diameter and oblateness has yet been found (see SUN: BASIC PROPERTIES).

Velocity fields

Solar-cycle changes in the surface rotation rate of the Sun are seen in Dopplergrams, and are traced by sunspots and other surface features. The Doppler data reveal a pattern of parallel belts of faster and slower rotation known as torsional oscillations, reminiscent of the butterfly diagram. Their amplitude is 5–10 m s^{-1} (i.e. 0.25–0.5% of the surface rotation), and the regions of maximal shear coincide more or less with sunspot latitudes. Whereas these belts were once thought of as being uninterrupted during the 16–20 years of their migration from pole to equator, persistent gaps at mid latitudes now suggest that their pattern is in fact more complex. Solar-cycle changes in the rotation rate of sunspots are larger (4–5%) and do not show evidence of latitude migration. The largest value of the sunspot rotation rate occurs at the sunspot minimum, and a smaller peak occurs at the sunspot maximum.

Doppler measurements also reveal a general poleward meridional flow of 10–20 m s^{-1} at all latitudes, with no visible solar-cycle modulation. A poleward drift of similar magnitude is seen in the motion of unipolar magnetic regions at high latitudes. Their velocity is largest around the solar maximum. The latitudinal drift of sunspots is typically 10 times smaller. It is not generally poleward, and can be different for leading and trailing spots. There is some evidence for a solar-cycle dependence.

Finally, there are indications for solar-cycle changes of the GRANULATION. At the solar maximum, size and flow speed of the granules seem somewhat reduced, but this modulation needs further confirmation.

Coronal indices and solar wind

The shape of the CORONA changes during the solar cycle. At the solar minimum it is elongated along the equatorial direction, and POLAR PLUMES can be seen. At the solar maximum, most of the disk is surrounded by CORONAL LOOPS and CORONAL STREAMERS, giving the corona a rounder shape. This increase of coronal activity at solar maximum is also evidenced by the number of coronal mass ejections and by the green coronal index (table 1; see SOLAR CORONAL MASS EJECTION: OBSERVATIONS). Some coronal indices vary out of phase with the sunspot cycle, and peak at the sunspot minimum. These include the number of polar FACULAE, SOLAR CORONA X-RAY BRIGHT POINTS and CORONAL HOLES. Coronal holes exist during most of the solar cycle and occur less frequently only during a few years near solar maximum.

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS1 6BE, UK

SOLAR PROMINENCES and SOLAR FLARES are phenomena related to SOLAR ACTIVE REGIONS, and their numbers vary in phase with the solar cycle. Solar wind speed and the spiral angle of the interplanetary magnetic field are slightly reduced during the solar maximum (table 1). This near-constancy of the SOLAR WIND may in part arise because it is fed with particles from both flares and coronal holes, the numbers of which vary out of phase with one another. However, the flux of high-energy solar particles is more strongly modulated because they are produced mainly by flares.

Extended solar cycle

The extended solar cycle is a concept based on the observation that several branches that are assigned to consecutive cycles can coexist in the butterfly diagram, and seem to be continuous across the solar minimum. The main example is the emergence of opposite-polarity bipolar ephemeral regions at high latitudes, 2–3 years before the solar minimum, apparently precursors of a new cycle. Also observations of the green coronal line, filaments, torsional oscillations, and the reversal of the polar field near the solar maximum may be mentioned. Dynamo theory suggests that such overlapping bands are a consequence of traveling wave fronts.

Terrestrial indices

The SOLAR–TERRESTRIAL CONNECTION is a wide and complex subject, and the implications of the solar cycle for the Earth's climate are controversial due to uncertainties of atmospheric physics and climate modeling. Out of the many solar–terrestrial correlations that have been proposed, only a selection is given here.

It is well established that the strength of the Earth's magnetic field, as measured by the AA index, varies in phase with the solar cycle. The field increase is attributed to compression of the Earth's magnetopause (see MAGNETOSPHERE OF EARTH: MAGNETOPAUSE) due to coronal mass ejections, the number of which peaks at solar maximum. The solar wind carries a magnetic field into interplanetary space, which provides enhanced shielding of COSMIC RAYS during solar maximum. The resulting solar-cycle modulation of the cosmic-ray flux at Earth is typically 50%. This is subsequently passed on to various other indices, including the rate at which radio isotopes are produced in the upper atmosphere. Measurements of the concentration of ^{10}Be in arctic ice cores and of ^{14}C in tree rings thus provide a unique tool for studying the history of solar activity. Due to different atmospheric storage times, the solar-cycle variations in these records are reduced to about 25% and 2% respectively. The 11-year signal in the ^{10}Be concentration follows the solar cycle with a delay of 0.5–1.5 years.

The number of AURORAS is related to the total particle flux emitted by the Sun, and it is weakly modulated by the solar cycle. Low-latitude auroras occur only around the solar maximum; they are attributed to flare-related high-energy particles, whose number peaks at the solar maximum.

Climate models indicate that the solar-cycle variation of the Sun's irradiation has only a marginal effect on terrestrial temperatures (about 0.05 K). A more likely solar-cycle influence on the Earth's climate, if present, would be chemical effects due to changes in the solar UV flux. Another possible cause is variations in cloud formation. They may arise from the solar-cycle modulation of the cosmic-ray flux, which affects the availability of condensation nuclei.

Examples of climate indices that show some evidence of a solar-cycle modulation are pressure scale height and temperature at low latitudes. The evidence for such modulations is, however, mostly based on a small number of cycles (often 1–2), which is probably insufficient. Also a remarkable anticorrelation between temperature on the northern hemisphere and cycle *length* has been found, but no mechanism is known that may account for it.

Stellar cycles

Magnetic cycles have been detected in other stars besides the Sun, as the result of a monitoring project conducted at Mount Wilson since 1966 (see SOLAR–STELLAR CONNECTION). For some 100 lower main-sequence stars regular measurements are made of the chromospheric Ca II H and K emission cores, which are known to have a magnetic origin from solar observations. Cyclic variations are found predominantly in old, slowly rotating stars of stellar types G-K, of which the Sun is one. Stars with well-defined activity cycles have cycle periods ranging from 7 to 14 years. Some stars have long-term activity trends that may turn out to be cyclic as the observations continue. Stars with a low and flat activity level may be in a grand minimum. They make up about a third of the total number of solar-type stars, which may be indicative of the fraction of time spent by the Sun in grand minima.

Origin of the solar cycle

The solar cycle is a magnetic phenomenon, and its explanation must come from dynamo theory, which concerns the generation of magnetic fields in conducting fluids. Theoretical difficulties have as yet prevented a satisfying, comprehensive explanation of the solar cycle. Nevertheless, several elements of the solar dynamo mechanism may be mentioned, that play an important role in most models.

Magnetic-field storage

As suggested by the Hale–Nicholson polarity rules, the prime cause of the solar cycle is an oscillating strong magnetic field (10^4–10^5 G) of predominantly toroidal orientation. This field can be stably stored not in the

Copyright © Nature Publishing Group 2002

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS1 6BE, UK

convection zone itself, but in the overshoot layer at the base of the convection zone (see SOLAR INTERIOR: CONVECTION ZONE). For sufficiently large field strengths a magnetic buoyancy instability sets in, which leads to the eruption of magnetic loops from the overshoot layer, their subsequent rise through the convection zone and, as a by-product, the emergence of bipolar pairs of sunspots at the solar surface (figure 4(*a*)).

Alpha effect

Convection or magnetic instabilities (see MAGNETO-HYDRODYNAMIC INSTABILITIES) can cause a magnetic flux element to rise or to sink. Due to the stratification of the atmosphere, a rising gas parcel, say, will generally expand. Through the Coriolis force, rotation provides this diverging flow pattern with a twist that is clockwise on the northern hemisphere and anticlockwise on the southern hemisphere. A sinking, contracting parcel acquires a twist of the opposite sense. The embedded magnetic field is also twisted, and thus poloidal loops may be formed around an initially toroidal flux element (figure 4(*a*)). This amounts to the creation of a net electric current parallel to the magnetic field, and is referred to as the alpha effect. Through the alpha effect, a net poloidal magnetic field is generated from the toroidal magnetic field.

Differential rotation

In the solar overshoot layer, rotation varies strongly with depth. This differential rotation, in turn, stretches the poloidal field into a strong toroidal field.

Dynamo mechanism

Both the alpha effect and the existence of an overshoot layer point to the crucial role played by convection in the solar dynamo. Together, the alpha effect and differential rotation maintain the solar magnetic field. They enable the formation of new toroidal flux elements of both polarities adjacent to an initial toroidal flux element. If this flux merges in a suitable manner, and if the differential rotation and the alpha effect have the proper sign, the net effect can be magnetic belts that migrate toward the equator. As the northern belt and the southern belt, which has the opposite polarity, meet at the equator, they both annihilate. At high latitudes, magnetic fields of opposite polarity, marking the beginning of a new cycle, may be formed a in this way (figure 4(*b*)). Thus, the solar cycle may be a traveling-wave phenomenon of the deep-rooted magnetic field.

The spatial distribution of magnetic flux at the solar surface may be largely explained by an additional flux transport model based on flux emergence in active regions, and surface transport by turbulent diffusion and meridional flow. Part of the magnetic energy can be released through various conversion mechanisms, and this leads to the broad range of solar-cycle modulations.

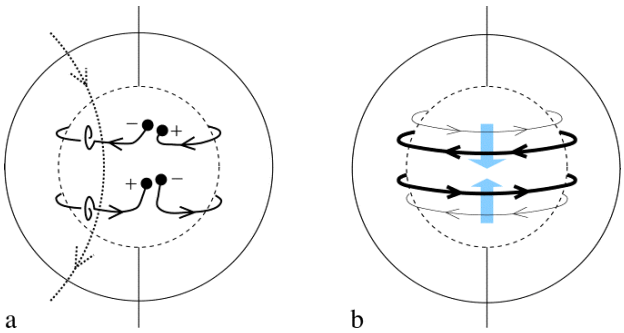

Figure 4. Diagram of the solar-cycle mechanism. The dashed circle represents the top of the radiative interior. (*a*) Generation of the poloidal field (dotted curve) from the toroidal field (drawn curve) by an alpha effect, and the formation of bipolar pairs of sunspots. (*b*) Migration and reversal of the toroidal field.

Breaking news update (30 April 2002)

Solar activity varies on a rough 11-year cycle with some cycles having more than one peak. The current activity cycle appears to be reaching its second peak. The most recent (and ongoing) solar max crested in mid-2000. Sunspot counts were higher than they had been in 10 years, and solar activity was intense. After that, sunspot counts slowly declined and the Sun was relatively quiet for month-long stretches. Solar max was subsiding. But now, activity has once again increased: the Sun is again peppered with spots, and eruptions are frequent.

Solar Evolution

It is generally accepted that the formation of the Sun arose from the passage of a shock wave through an interstellar cloud (see, for example, INTERSTELLAR MATTER), causing part of the cloud to become gravitationally bound. The major component of the cloud was hydrogen, together with about 25% helium, and more massive elements in minor proportions.

On contraction of the cloud, half the kinetic energy so produced caused an increase in its temperature and half was lost as radiation. The stages in solar evolution are effectively illustrated by the HERTZSPRUNG–RUSSELL DIAGRAM, a plot of the logarithm of the surface temperature against the logarithm of the luminosity. The pre-main sequence phase, in which the contracting cloud began to emit as a cool, luminous star, lasted some 10^7 years (see PRE-MAIN-SEQUENCE STARS). With further contraction and a consequent increase in temperature, fusion of hydrogen nuclei to helium became the dominant process, the energy released halting contraction and maintaining the core temperature at approximately 12×10^6 K. This stage in the evolution of the Sun is referred to as the zero-age main sequence, the effective point at which the Sun can be considered as a star.

The subsequent main sequence phase, during which the Sun continues the fusion process of hydrogen to helium, has an estimated duration of 10^{10} years, and is characterized by a slow expansion of the Sun together with a steady increase in luminosity. The main sequence phase will cease when the hydrogen in the core has been exhausted, and the Sun will evolve into a red giant, then a red supergiant and finally to a white dwarf star (see RED GIANT STARS, WHITE DWARFS and STELLAR EVOLUTION).

Solar Feeds

Observations of the Sun typically involve modest aperture and a large and heavy spectrograph. In the field at ECLIPSES the telescope itself may need to have a long focal length. These requirements are conveniently met by having a tracking flat mirror which feeds a stationary telescope and its instrumentation. Magnetograph observations, which involve the polarization analysis of spectrum lines, place an additional constraint by demanding that the imaging system introduce a minimum of polarization. Geographic latitude of the site is another factor. These various considerations have led to a variety of what may be called 'solar feeds'.

A mirror which tracks a celestial object and delivers the light in an arbitrary but fixed direction is called a *siderostat*. In general, the mirror must move at a non-uniform rate, the image field rotates non-uniformly and linear polarization results from the oblique mirror reflection. Percentage polarization increases with the angle of reflection.

If the optical path is confined to the polar axis, either by placing the telescope there or by introducing a second mirror, conditions simplify and we have a *heliostat*. For the heliostat the polar axis of the mirror turns at the diurnal rate and the change of declination for the Sun is accommodated as in a conventional EQUATORIAL MOUNTING. The image plane unfortunately also rotates at the diurnal rate. This means that for other than short exposures the instrument package (spectrograph) must co-rotate. Also the amplitude of introduced feed polarization is constant during the day (ignoring any second flat), but its plane rotates.

If the mirror surface is parallel to the polar axis we have a *coelostat*, figure 1. Now either the telescope must move in angle in the meridian plane or, more commonly, a second mirror is introduced which must translate for objects at different declinations to intercept the beam and direct it to the stationary telescope. The coelostat mirror rotates at half the diurnal rate. Most important the image plane does not rotate, although it does change if the second mirror is translated. Compared with a heliostat, the per cent polarization may be less depending on mirror positions, although it will vary through the day.

Because of the deleterious effects of feed polarization, particularly for full vector magnetographs, and taking into account the availability of CHARGE-COUPLED DEVICE (CCD) arrays which mean smaller image scales, the present trend is toward compact systems in which the entire telescope points at the Sun. This avoids oblique reflections and is achieved by *altazimuth* or *equatorial* mounts.

Solar mirror feeds remain popular for eclipse work. For a site near the equator a heliostat is convenient since the exposures are short and the telescope nearly horizontal, figure 2. A coelostat, with its fixed image, is well suited for observations near the solstice, since declination change is then at a minimum. If an altazimuth mounting is considered, remember that the Sun disappears at totality where no guiding is possible.

Figure 1. Large coelostat feed for the Kitt Peak Vacuum Telescope. Here the number 2 mirror is adjustable in height and angle only. The coelostat itself swings along a circular path to account for seasonal and diurnal change. This scheme was first used at the Potsdam Observatory in Germany.

Figure 2. Eclipse site near the equator with a heliostat arrangement.

Other solar feeds include the *polar siderostat*, which is the same as a heliostat except the beam is directed toward the pole, and the *uranostat*, which is a siderostat which operates or tracks correctly only near the meridian (see also SIDEROSTAT/HELIOSTAT/COELOSTAT).

Solar Filament Channels

A filament channel is a magnetic rift that runs through the chromosphere along the base of a solar filament and beyond either end. Because the filament and its channel separate magnetic fields of opposite magnetic polarity at the solar surface, field lines will cross over them at some height as an arcade of closed loops. A channel is a rift in the sense that it partitions positive and negative fields by directing its own magnetic field predominantly along, rather than across, a horizontal, axial direction. A channel develops before its filament forms and can outlive it by a large margin. Channels are therefore an essential ingredient of the prominence-forming environment (see SOLAR PROMINENCE FORMATION). Although filament channels were first recognized 30 years ago, investigations into their origins are recent. We now believe that both filaments and their channels derive from the evolution of surrounding magnetic fields at the solar surface.

The clearest signature of a channel is a pattern of chromospheric fibrils (see CHROMOSPHERE: FIBRILS) aligned in a band along a magnetic polarity boundary. This pattern is not present at every polarity boundary; the bands of fibrils appear only where overlying magnetic fields are suitably configured to form and support a solar filament. Not every filament channel contains a filament, nor does every polarity inversion develop an associated channel. The term polarity inversion line (PIL) signifies a line traced along the photospheric surface where the normal component of the magnetic field ($B_{\|}$) reverses sign. The visibility of a channel depends upon the strength of the fields adjacent to its PIL.

Historical background

Dark chromospheric filaments have been familiar for over a century as bright prominences at the limb carried onto the solar disk by the Sun's rotation (see SOLAR PROMINENCES). Yet channels were, until recently, overlooked, chiefly because they are often veiled by optically thick matter in their overlying filaments. They need to be viewed in large-scale images (resolution $\sim$1") at wavelengths where filaments become optically thin. Furthermore, the significance of filament channels was not appreciated until chromospheric images could be compared with maps of the underlying photospheric magnetic fields.

Solar astronomers have long observed the entire chromospheric surface by making monochromatic images in the core of the strongest Fraunhofer absorption lines, usually the Balmer α line of hydrogen and the H and K resonance lines of ionized calcium. Instruments used for this purpose are either the spectroheliograph or the tunable birefringent monochromatic filter (see SOLAR TELESCOPES AND INSTRUMENTS: GROUND). The resulting images are recorded as spectroheliograms and filtergrams, respectively. Observers frequently liken extensive patterns of short dark fibrils in Hα images to patterns of iron filings sprinkled over a sheet of paper placed above a bar magnet. The mapping of magnetic fields anywhere on the Sun thus became a motivating factor for the invention of the solar magnetograph in the 1950s by H W and H D Babcock (see SOLAR MAGNETIC FIELD: INFERENCE BY POLARIMETRY). The magnetograph's mapping capacity led to their discovery that solar filaments are located along PILs.

Where a PIL passes between bright chromospheric plages of opposite magnetic polarity (see SOLAR CHROMOSPHERIC: PLAGES), its corresponding filament is shorter and narrower than a quiescent prominence (see SOLAR PROMINENCE OBSERVATIONS) surrounded by weak fields. When observed at wavelengths with lower optical thickness in the chromosphere than the core of Hα, a channel surrounded by strong fields appears as an elongated void conspicuously free of absorbing structures. It is also called a plage corridor, or plage couloir, following M-J Martres and her colleagues at Meudon Observatory, who first described the phenomenon in the 1960s.

Solar magnetographs were few and far between in the early years of space exploration; even fewer could measure all the Stokes parameters for deriving vector magnetic fields to test SOLAR FLARE MODELS. Pressing demands to forecast trends in solar activity, both in the long and short term, stimulated attempts in the 1970s to use monochromatic Hα images in conjunction with maps of $B_{\|}$ as a proxy for a chromospheric vector magnetograph. H Zirin and co-workers at Big Bear Solar Observatory (BBSO) coined the term *chromospheric magnetograph* and championed the method as a viable option for inferring field directions in some magnetic configurations from Hα filtergrams. The Hα line has the combined advantages of large opacity and large scale height at a geometrical height where magnetic flux tubes, penetrating the surface, rapidly expand laterally to form a magnetic canopy (see CHROMOSPHERE: MAGNETIC CANOPY). Accordingly, the coarser fine structures in Hα, being nearly horizontal wherever conditions favor canopies such as the borders of plages or the outer chromospheric reaches of sunspot penumbrae (the *superpenumbra*), indicate the location and direction of the transverse component of the local magnetic field in the chromosphere.

Because large-scale patterns of solar magnetic activity evolve slowly, i.e. often lasting many days, Hα filaments and patterns of Hα fibrils follow suit even though they may dissolve or erupt and then reappear several times in response to small local changes. Evolutionary changes are slow enough that a panoramic, or 'synoptic', view can be constructed from the daily Hα filamentary structures to summarize the distribution of magnetic activity at each longitude during a full rotation of the Sun. P S McIntosh pioneered the use of *synoptic maps* based on Hα observations to forecast trends in solar activity from one solar rotation to the next. He recognized magnetic polarity boundaries as key structural elements for describing how global surface activity is organized. To infer their locations he used filaments, plage corridors, emerging flux regions with arch filament systems (see CHROMOSPHERE: EMERGING FLUX REGIONS), and alignments of Hα fibrils. Patterns of

aligned fibrils extending axially far beyond either end of a filament, or patterns of axially aligned fibrils without a filament forming among them, were called 'filament channels' by McIntosh. In his accompanying synoptic map (figure 1) channels are shown as dashed lines joining Hα filaments. They are extrapolated to form proxy PILs which wind their way through, around, and between solar activity complexes, over vast distances.

Chromospheric properties of filament channels in strong background fields

The earliest descriptions noted an inverse relation between the width of chromospheric corridors and the strength of the field gradient across their corresponding PILs. This effect is illustrated by three channels in the small activity complex of figure 2. Two sunspots, S1 and S2, of following (black) magnetic polarity (see SUNSPOT CLASSIFICATIONS) in the magnetogram in panel C mark the locations of the strongest concentrations of flux in this complex. The remaining flux is distributed among plages of both leading (white) and following magnetic polarities: bright Hα plages in panel A coincide with strong flux concentrations outside of the sunspots in C, faint plages with the weaker flux concentrations. Three Hα filaments (F1, F2, F3 in panels A and C) and three corresponding channels (C1, C2, C3 in panel B) separate plages, or plages and sunspots, of like polarity from plages of opposite polarity. The narrowest channel, C2, is a narrow crack about 1 Mm wide among the optically thick absorbing structures just above the characters 'C2' in panel B; it is located close to spot S1 at a PIL within a steep gradient of $B_{\parallel}$. The widest channel, C3, appears as a broad void between absorbing features in panel B, and over a PIL with a shallow gradient between widely spaced flux concentrations. A channel of intermediate width, C1 in panel B, separates two bright plages.

A more exact description of a chromospheric channel includes the orientation of Hα fibrils along its fringes. In figure 2, fibrils rooted in the bright plage above channel C3 (panel B) are oppositely inclined to the fibrils rooted in the fainter plages of opposite magnetic polarity below C3, as indicated by the curved arrows. P Foukal first drew attention to such patterns where Hα fibrils are oppositely oriented on either side of a filament channel. He concluded that this characteristic pattern arises from a magnetic field with a predominantly horizontal component along, and not across, the axial direction of the channel.

S Martin and associates at BBSO applied Foukal's result to many quiescent filaments and their underlying channels. They discovered a hemispheric asymmetry for filaments based on the patterns of oppositely oriented fibrils. When channels are viewed from the positive polarity side, a majority in the northern (southern) hemisphere have fields directed to the right (left) as determined from the orientation of the fibrils fringing the channel. Thus the channel field has a definite orientation—either dextral or sinistral—which predominates in the northern and southern hemispheres

respectively. Channels with a common orientation can join to form very long and very persistent structures. Channels can exceed in length and duration any filament which forms within them.

Chromospheric properties of filament channels in weak background fields

Filament channels, seen as aligned bands of Hα fibrils, are seldom found alongside quiescent filaments which border the Sun's polar caps or, more generally, in weak magnetic fields. The example in figure 3 (middle panel) contains Hα filaments formed in segments along a single outstretched PIL which winds from high to low latitudes around an extended area of predominantly negative (black) polarity flux (figure 3, bottom panel). Because this PIL reverses direction in an east–west sense by bending around a centre of curvature located to the west of the reversal, it is called a *switchback*. Fibrils next to the filaments in the polar arm (polar crown filaments, or PCFs) are not preferentially aligned with respect to the PIL; fibrils in the arm at lower latitudes do align strongly with the PIL in the dextral orientation, which is characteristic of a filament channel in the northern hemisphere. White contours in each panel of figure 3 outline narrow arteries following several PILs (with and without filaments) of reduced absorption in the He I line at λ1083 nm (upper panel). Brightness inside these arteries is comparable to that of the small CORONAL HOLE outlined in black at the right-hand edge of each panel. The bright He I arteries, considered equivalent to Hα filament channels because they correspond closely in width and location in stronger fields at lower latitudes, have the advantage of remaining visible among weak magnetic fields elsewhere.

Yet the Hα and He I signatures of channels differ in essential characteristics. The Hα signatures have a radiative and a morphological component: a void observed at wavelengths where the Hα line is optically thin informs us about chromospheric excitation conditions along a PIL, while the orientations of fibrils inform us about the geometry of the magnetic field in the chromosphere at a PIL. The He I signature is primarily a radiative one from a more complex regime of densities and temperatures characteristic of both the chromosphere and the corona. The same can be said for other diagnostics which have been applied in the recent past to the detection of filament channels at wavelengths ranging from soft x-rays to sub-millimetre radio waves.

The absence of an Hα signature for a filament channel at a PCF is probably due to weaker ambient magnetic flux densities and to their greater height relative to the corresponding factors for a quiescent filament at lower latitudes. But an elevated axial field of a PCF can leave its imprint on the chromosphere in other ways: the horizontal field inhibits downward (i.e. cross-field) heat conduction from the corona, thereby affecting the balance and transport of energy directly beneath it. For example, the λ1083 nm line of He I forms through an interplay between direct collisional excitation of the relevant energy levels of He I within the ambient plasma and photoionization–recombination of those same levels driven by overlying coronal sources (see SOLAR SPECTROSCOPY AND DIAGNOSTICS). Obstruction of downward heat conduction could, in principle, contribute to the reduced absorption seen as a bright He I artery at a PCF. The actual mechanism that dominates the formation of the λ1083 nm line can be determined from models, provided that the local circumstances are properly defined. Here atmospheric inhomogeneities play significant roles, the most relevant being the CORONAL CAVITY—plasma at coronal heights enveloping a prominence where density rather than the coronal temperature is reduced. H S Hudson, K L Harvey and associates have recently used simultaneous observations in soft x-rays (Yohkoh/Soft X-ray Telescope) and the λ1083 nm line of He I (National Solar Observatory, Kitt Peak (NSO/KP)) to show that the outer boundaries of a coronal cavity coincide with the boundaries of a bright He I artery at a filament channel. The chief factor responsible for locally weakening the λ1083 nm absorption and thereby creating a bright artery is, according to this evidence, the reduced coronal illumination from the rarefied cavity overlying the filament channel. Further simultaneous, multiwavelength

observations with space- and ground-based instruments will soon be forthcoming to clarify the link between chromospheric filament channels and coronal cavities.

Creation of filament channels

The initial conditions for creating a filament channel—based on empirical criteria identified in the 1980s by S F Martin—are the same as those for solar prominence

formation: mass flows transporting magnetic flux of opposite polarities to a PIL, cancellation of opposite polarity flux in these converging flows, and a magnetic arcade overlying the PIL. During the process of formation, magnetic shear is created above the PIL, i.e. the magnetic field in a vertical plane above a PIL departs from an ideal potential (current-free) configuration (see MAGNETOHYDRODYNAMICS). This departure is manifestly obvious in the axial alignment, described above, of chromospheric fibrils in a filament channel.

Models of solar prominence formation have been put forward over many years; not until the past decade have any addressed the formation of filament channels. Opinion about the formation of channels is divided between two main schools of thought (see SOLAR PROMINENCE MODELS). One school creates a channel at the solar surface by converging mass flows of already emerged magnetic elements onto a PIL so that oppositely directed field lines of the surrounding arcade reconnect but only the axial component survives. The other school produces an axial component of the field below the surface by making differential rotation act on subsurface magnetic fields (see SOLAR INTERIOR: ROTATION). In the latter case the filament channel forms when the subsurface axial field emerges at a PIL. Of the two hypotheses, the first is more amenable to direct observational tests.

The most complete observational description to date of a channel in the act of formation, by V Gaizauskas, J B Zirker, C Sweetland and A Kovacs, supports instead a process by which an existing magnetic topology at the surface readjusts to the arrival and rapid evolution of new magnetic flux from below. In this scenario, an existing slowly decaying bipolar plage trails behind a large field-free area in which new flux emerges not as a single bipolar region but as two, arriving in quick succession and almost on top of one another, thereby forming a compact activity complex. The placement of the bipoles, old and new, results in a regular alternation of magnetic polarity along almost the same parallel of latitude, thus ensuring a PIL between the existing plage and the new cluster of sunspots. The nearly superposed emerging bipoles create a highly non-potential magnetic configuration with nearly horizontal field lines low in the atmosphere. Normal evolutionary expansion of the new active regions then drives this configuration with its strong horizontal field component towards the PIL.

The visible result of these actions appears at the extreme left of figure 4(*a*) as an alignment of many Hα fibrils which happen to be superposed on a PIL. That alignment develops within a few hours which coincide with rapid growth of the second bipole in the compact activity complex. These Hα fibrils stream in opposite directions on opposite sides of that PIL—thus confirming that the aligned pattern is a filament channel. According to the Hα observations the channel is maintained on succeeding days. But it takes three more days before a filament forms in it. By using a force-free approximation (see FORCE-FREE MAGNETIC FIELDS) to model the magnetic field due to this distribution of magnetic sources, D H Mackay was able to fit the pattern of fibrils with a system of horizontal loops (figure 4(*b*)). The flatness of the magnetic loops is emphasized in the oblique view of figure 4(*c*). Mackay also applied the force-free model to represent the filament itself, and showed that the representation would fail without the presence of the pre-existing plage. This combination of observations and models shows that it is possible to attribute the formation, at least among active regions, of a filament channel and a filament entirely to normal evolutionary processes acting on flux after it has emerged. No recourse is needed to a hypothetical submerged flux rope.

Although this channel and its filament are small their environment is a typical one within the belts of active latitudes—new flux emerging in an activity complex next to decaying flux. They are special only in the fact that emergence occurred in an area free of any magnetic activity which could have complicated and confused the evolving patterns of chromospheric fibrils. The real merit

Copyright © Nature Publishing Group 2001

of this example lies in hinting at an alternative source for providing magnetic fields with a strong horizontal component: currents associated with emerging activity complexes that distort the magnetic topology into a highly non-potential configuration. Horizontal fields are naturally resistant to decay or to submergence, although they will disrupt due to plasma instabilities of various kinds (see SOLAR PROMINENCE ERUPTION). When confined as channels at a PIL they can also be replenished by reconnections between numerous canceling magnetic elements converging onto the PIL.

So one way to produce channels on the scale and duration of the ones outlining the switchback of figure 3 is to link up channels with common orientation that have been created in the belts of active latitudes by flux emergence of many neighboring activity complexes and then transport them poleward. The push can come from migrating flux driven poleward by large-scale emergences of new flux at lower latitudes combined with meridional flows. In this scenario filaments at the polar crowns are created when the migrating flux reconnects with fields already present in the polar caps. At polar latitudes an arcade overlying the PIL between the polar cap and an approaching surge of migrating photospheric flux arches well up into the corona. Field lines anchored in converging, sheared photospheric flows of opposite polarity flux near the polar caps are thus more likely, on reconnection, to leave an axial field suspended in the corona well above the chromosphere. In effect, the 'channel' for a polar crown filament as defined by the axial field leaves little or no imprint on the chromosphere, which is consistent with the situation illustrated in figure 3.

The elegant model of global flux transport by van Ballegooijen, Cartledge and Priest contains some of these features but does not include any role for reconnection of field lines in arcades overlying PILs to produce the axial horizontal field. The combined effects in this model of differential rotation, magnetic diffusion (random dispersal of magnetic elements by supergranulation (see SOLAR PHOTOSPHERE: SUPERGRANULATION)), and meridional flows acting on distributions of flux emerging at low latitudes result in axial fields located around switchbacks as observed. The orientation of the axial fields in the low-latitude diagonal arms of switchbacks derived from their model is consistent with the global organization of the orientation of channels found by Martin, Bilimoria and Tracadas. However, the orientation of channels in the arms of switchbacks at the polar crown predicted by this model of global flux transport are in conflict with observations. Some essential aspects are still missing in the physics of formation of the axial field in polar crown filaments. New observations made simultaneously from spacecraft and the ground of polar crown filaments are already planned to identify the missing ingredients.

Solar Flare Classification

SOLAR FLARES are classified according to their size, duration, morphology or magnetic topology and the composition of their associated energetic particles. This article will cover the more enduring and comprehensive of these various classification schemes.

Solar flares are wonderfully complex phenomena and are observed across the electromagnetic spectrum as well as via energetic particles in space. The first reports of a flare, observed in white light by Carrington and Hodgson in 1859 (see SOLAR FLARES: WHITE LIGHT), captured their essence as transient energy releases in SUNSPOT regions. Following Hale's invention of the spectrohelioscope during the 1920s, flares were extensively studied in the Hα emission line. The 1940s saw the first observations of flare-associated radio and particle emissions and during the space age the full gamut of flare x-ray, extreme-ultraviolet and gamma-ray data (SOLAR FLARES: GAMMA RAYS) became available along with observations of accompanying transient coronal activity.

Not surprisingly, the successive opening of new observational windows to the flare phenomenon has resulted in the development of classification schemes particular to given wavelengths. These classification schemes encompass flare size and morphology, and, in the case of flare-associated energetic particles, the particle composition. If there is one overarching theme, it is that solar flares, despite their seemingly infinite variety, come in two basic flavors—impulsive and gradual. Impulsive flares have time scales of the order of a few minutes or less while gradual flare durations range from tens of minutes to several hours. These two basic types are combined in fully developed flares in which an impulsive phase is followed by a gradual main phase (see SOLAR FLARES: IMPULSIVE PHASE; SOLAR FLARES: MAIN PHASE). The time scale (gradual versus impulsive, short versus long-duration) distinction between the two basic kinds of flares has been noted by investigators working in virtually every wavelength and energy range. During the 1970s, it became appreciated that these time scales were indicative of magnetic topology; long-duration flares were linked to SOLAR CORONAL MASS EJECTIONS (CMEs) and impulsive flares were thought to be completely confined within the Sun's lower atmosphere. Today it is recognized that some short-duration flares may also have ejecta. Nevertheless, the concept of two fundamental types of flares (impulsive/short duration/confined versus gradual/long duration/eruptive) frames current thinking on this subject.

Size classification of solar flares: Hα and soft x-ray

There are only two widely used classification systems that address flare 'size' or 'importance'. The first of these is the Hα classification scheme (table 1) that was developed during the 1930s. It consists of a character (S = subflare, or 1, 2, 3, or 4 for successively larger flares) that denotes the flare size and a letter (f = faint, n = normal, b = bright) corresponding to a subjective estimate of the intensity of the emission. Thus the most outstanding flares are classified as 4b and the smallest and faintest as Sf. In general, the larger the optical classification of a flare, the more likely that it is a gradual (long-duration) or eruptive flare, but this is only a rule of thumb.

Table 1. Optical classification of solar flares.

Importance class	Area (A) at disk center (millionths of a solar hemisphere)
S	$A < 100$
1	$100 \leq A < 250$
2	$250 \leq A < 600$
3	$600 \leq A < 1200$
4	$A \geq 1200$

A second size classification that has come into common usage since about 1970 is based on soft x-ray observations of the Sun in the 1–8 Å band by Earth-orbiting satellites. The size of the flare is given by the peak intensity (on a logarithmic scale) of the emission. Flares are classified with a letter (A, B, C, M or X) corresponding to the power of 10 (-8, -7, -6, -5, -4, respectively) of the peak 1–8 Å flux in units of W m^{-2} and a number (1–9) that acts as a multiplier. For example, a B3 flare has a peak flux of 3×10^{-7} W m^{-2} and an M8 flare has a peak flux of 8×10^{-5} W m^{-2}. Generally, flares smaller than C1 can only be detected during a SOLAR CYCLE minimum when the x-ray background is low. Flares occasionally exceed class X9 in intensity; they are simply referred to as X10, X11 etc events. Note that the soft x-ray classification gives no indication as to whether the flare is eruptive or compact. While there is a general tendency for intense flares to be eruptive, X-class flares can be confined and B-class flares can have CME associations.

Classification of flares in terms of magnetic topology: confined versus eruptive

The discovery of coronal mass ejections in about 1970 gradually led to a profound change in the way that solar astronomers think about flares. The word 'flare' implies an event that is localized within an active region while CMEs leave the Sun at speeds of up to 2000 km s^{-1} and can have angular spans that encompass several active regions. At first it was thought that CMEs were blown out by the explosive release of energy during the flare, whereas today the prevailing view is that eruptive flares are a consequence of CMEs. Figure 1 captures much of the rich phenomenology associated with eruptive flares. The essential aspect from a flare classification point of view is that magnetic field lines are opened by CMEs in eruptive events. The closing down or reconnection of these newly opened field lines typically occurs on a time scale of hours and provides the prolonged energy release characteristic of gradual or eruptive flares, although it must be noted that CMEs can also be accompanied by short duration flares. As can be seen in figure 1, the intersection of the

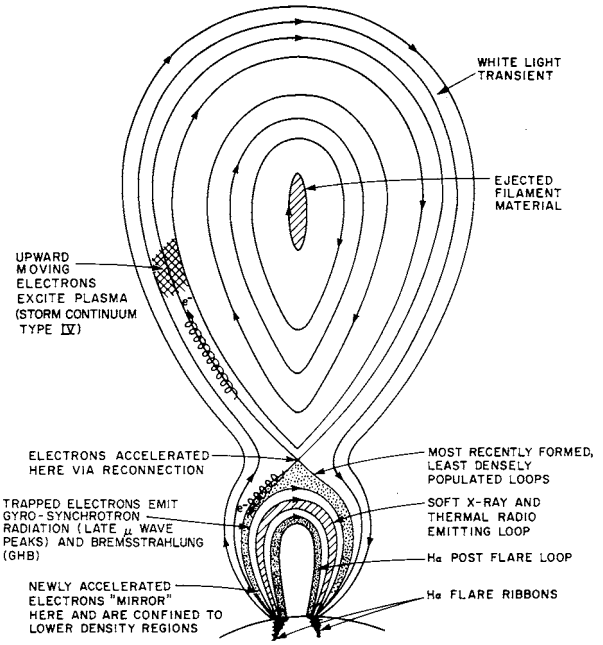

Figure 1. Magnetic topology of a gradual or eruptive flare (from Cliver *et al* 1986 *Astrophys. J.* **305** 920).

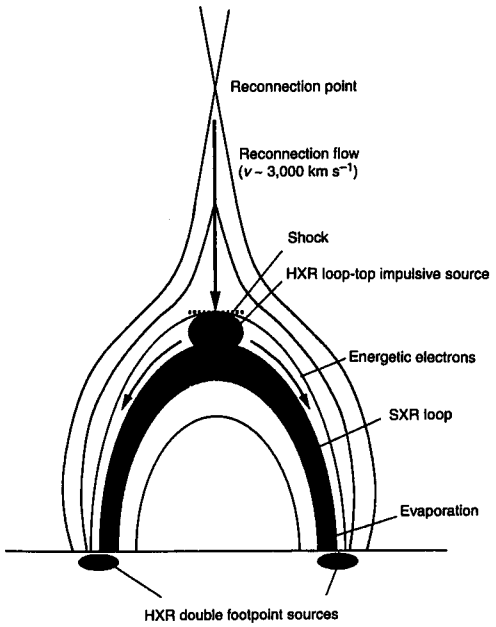

Figure 2. Magnetic topology of an impulsive or confined flare (from Masuda *et al* 1994 *Nature* **371** 495).

newly formed flare loops (or 'post-flare' loops as they were previously called) with the solar surface is marked by two parallel ribbons in Hα. Thus, before the role of the CME was fully appreciated, eruptive flares were referred to as two-ribbon or double-ribbon events. This type of flare morphology is also observed in association with eruptive prominences outside active regions (such events are often referred to by the French term 'disparition brusque'). Today it is generally thought that the basic physics of eruptive prominences and large two ribbon flares is identical and both phenomena are referred to as eruptive flares.

While eruptive flares attract much attention because of their size, complexity and association with GEOMAGNETIC STORMS and Forbush decreases of cosmic ray intensity, they comprise only a small fraction of all flares. The vast majority of flares are short-lived or impulsive events that lack CMEs. Such flares were traditionally modeled in terms of energy release within a single static magnetic loop and were thus referred to as single-loop, point, compact or confined flares. However, recent images of flares in energetic x-rays have indicated that confined or impulsive events may also result from loop top magnetic reconnection as shown in figure 2. In that case, the difference between the eruptive and confined classes of flares may be more one of degree than of kind, since the reconnection event depicted in figure 2 will result in the detachment of a narrow magnetic loop into the SOLAR WIND. The idea that the particle acceleration process is similar in impulsive and eruptive flares (or in the impulsive and gradual phases of fully developed flares) finds some support from gamma-ray observations that indicate similar compositions of interacting particles for both types of events.

The most important flares in terms of their geophysical consequences are large fully developed events in which an impulsive phase is followed by a gradual main phase. Such 'hybrid' flares are classified according to their end phases as eruptive flares. Occasionally, disparition brusque events, which represent a 'pure' form of eruptive flares, can also result in severe magnetic storms.

Classification of meter wavelength radio bursts associated with flares

Solar flares have associated radio events, or 'bursts', at wavelengths ranging from millimeters to kilometers. The radio burst classification scheme developed during the 1950s by Australian and French solar radio astronomers has proven to be particularly useful in terms of the current division of flares into confined and eruptive categories (see SOLAR FLARES: RADIO BURSTS). A schematic of the meterwave dynamic spectrum corresponding to a large eruptive flare is shown in figure 3. In terms of the eruptive/confined classification scheme, burst types III and V are characteristic phenomena of impulsive flares (or the impulsive or initial phase of fully developed eruptive flares). Type III bursts and their associated type V continua are attributed to flare-accelerated electrons moving along open field lines into the corona. Type II and type IV bursts are most commonly identified with eruptive flares. Type II or 'slow-drift' emission indicates a shock wave moving out through the corona with a characteristic speed $\sim$500 km s^{-1}. The shock exciter is either a flare-initiated

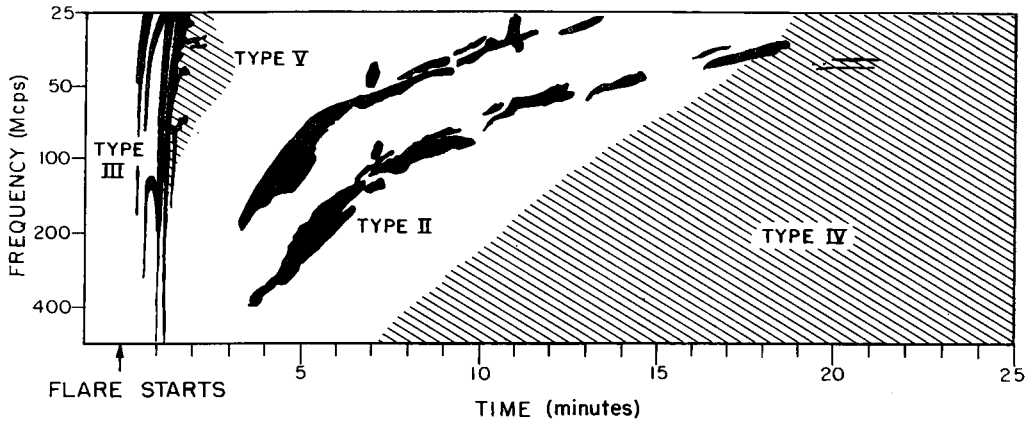

Figure 3. Metric radio emission associated with a fully developed eruptive flare.

blast wave or a CME. Type IV emission is thought to result from magnetic reconnection in the wake of the CME (figure 1).

Classification of solar energetic particle events

The energetic particle ($E > 1$ MeV/nucleon) events observed in space following flares were one of the last aspects of flares to be brought under the two-class picture (see SOLAR WIND: ENERGETIC PARTICLES). Prior to about 1985, there were a number of abundance anomalies associated with solar particle events that defied organization. These included a wide range of variation in electron (e) to proton (p) ratios, ^{3}He/^{4}He ratios and Fe/O ratios. In the mid-1980s it was recognized that flare time scale was a useful parameter that could order the data. In general, it was found that particles from impulsive flares have higher e/p, ^{3}He/^{4}He and Fe/O ratios than those recorded for 'normal' particle events (which include virtually all large events) that are associated with long-duration flares. In addition, heavy ions in large events have relatively low charge states corresponding to 2 MK temperatures, indicating acceleration high in the CORONA and in the solar wind rather than in hot (10 MK) flare plasma. Energetic particle events associated with eruptive flares can be observed over a much wider range of heliolongitudes than is the case for confined flares. Thus these large events are attributed to acceleration by coronal/interplanetary shocks driven by CMEs. Distinctions between impulsive and gradual events may be blurred in hybrid particle events for which both flare and shock components are observed. The current two-class picture of SEP events is summarized in table 2. The usage of 'impulsive' and 'gradual' in this table refers to both the flare and particle event duration.

Table 2. Properties of impulsive and gradual energetic particle events and their associated flares.

	Impulsive	Gradual
Particles:		
e/p	Electron-rich	Proton-rich
^{3}He/^{4}He	∼1	∼0.0005
Fe/O	∼1	∼0.1
H/He	∼10	∼100
Fe charge state	∼20	∼14
Duration	Hours	Days
Longitude cone	<30°	180°
Flare:		
Type	Confined	Eruptive
Radio bursts	III/V	II/IV
Soft x-ray duration	<1 h	>1 h
CME?	—	Yes
Interplanetary shock?	—	Yes
Events/year	∼1000	∼10

Open questions and ongoing research

The separation of flares into two distinct classes has proven to be a useful framework that organizes a great deal of disparate data. At the same time, many key questions remain unanswered. A sampler of some of these open questions follows:

(a) While the relationship of CMEs to long-duration flares is generally interpreted in terms of magnetic reconnection, the role of CMEs in impulsive flares remains unclear. Nor is the relationship of the impulsive phase to the gradual phase in large fully developed flares understood. Does the impulsive flare serve to trigger a larger-scale eruption?

(b) There is some evidence that CMEs associated with prominence eruption events have different acceleration profiles from CMEs that accompany eruptive flares in active regions. Specifically, flare-associated CMEs undergo much more rapid acceleration than CMEs associated with disparition brusques. The basis for this difference is not understood and requires further investigation.

(c) The origin of the coronal shocks manifested as metric type II bursts remains a matter of controversy, with advocates for both flare and CME causes. The source of the chromospheric Moreton waves (or the waves imaged in extreme-ultraviolet wavelengths in the

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

corona) that have been identified with type II shocks is similarly unclear.

(d) Does the magnetic topology for gradual or eruptive flares depicted in figure 1 apply to all such events? In particular, there is a controversy as to whether magnetic reconnection is required for the formation of the magnetic flux ropes (corresponding to the upper 'disconnected' structure seen in cross section in figure 2) that are observed in interplanetary space.

(e) Does the magnetic topology for impulsive flares depicted in figure 2 apply to all such events? Intense impulsive flares are frequently observed that lack type III emission; this is contrary to expectation, given the open field lines at the acceleration site in the model.

(f) Can coronal/interplanetary shocks accelerate particles to the tens of GeV energies occasionally observed in solar particle events?

Solar Flare Forecasting

Like weather forecasting, solar flare forecasting (or forecasting solar activity in general) is motivated by pragmatic needs. Solar flares, coronal mass ejections, solar winds and other solar activity intimately influence the near-Earth space environment. All kinds of spacecraft including weather and communication satellites are orbiting Earth, and their performance and lifetimes are greatly influenced by solar activity. High solar activity increases the density of the stratosphere, which increases the atmospheric drag of low-Earth-orbiting satellites. In planning manned space activity such as space station fabrication and interplanetary travels, one must consider harmful effects of solar energetic particles and radiations.

Even on the ground, we are not free from the influence of solar activity. The Great Quebec Blackout of 13 March 1989 was caused by a big solar flare and its associated phenomena. When the geomagnetic field is abruptly changed by a magnetic cloud crashing onto it or by an interplanetary shock wave, strong electric fields are induced in large-scale electric power distribution systems. The blackout was a result of such a process. Additionally, geomagnetic storms make a compass useless for navigation. Short-wave communication is hampered when the ionosphere is disturbed by energetic UV and x-radiations.

In deploying solar experiments, one should also consider the level of solar activity. Spacecraft containing instruments for solar activity are usually launched near solar cycle maxima. For the same reason, it is better to launch a balloon carrying instruments for investigating solar flares during or just before an episode of high solar flare activity, if possible.

Even long before the advancement of meteorology, people began to forecast weather on the basis of phenomenology. Likewise, even though we do not fully understand the underlying mechanisms for various manifestations of solar activity, we should make best of our current knowledge in order to forecast solar activity more reliably.

Long-term forecasting

We utilize our knowledge of the local climate and seasons in order to predict the local weather far in the future. Likewise we can utilize the 11 yr sunspot cycle in order to predict the level of solar activity far into the future. The phase and the strength of the sunspot cycle are relevant information. However, the length of the 11 yr cycle, unlike the length of a year, is not fixed but can vary abruptly in a range from 7.3 to 17.1 yr. The maximum sunspot number is also highly variable from one solar cycle to the next. In spite of these, various empirical rules, although not strict, have been utilized to predict the upcoming sunspot cycle. For example, it has been noticed that an odd-numbered cycle is usually stronger than the preceding even cycle. (The sunspot cycle which peaked in the year 1760 is defined as cycle 1.) Inspecting the strengths of cycles 1–21, we find that this rule has been observed by all the even–odd pairs except two pairs (cycles 4 and 5, cycles 8 and 9). It remains to be seen whether cycle 23, which is expected to reach its maximum in the year 2000, is going to be stronger than cycle 22. However, considering the chaotic nature of sunspot cycles, which is inherent to many nonlinear systems, we cannot be sure. (See SOLAR ACTIVITY: LONG-TERM RECORDS.)

Another empirical rule is that a cycle of larger-than-average size usually follows a cycle of shorter-than-average period, while a cycle of smaller-than-average size usually follows a cycle of longer-than-average period. By the end of one sunspot cycle, one can guess the strength of the next sunspot cycle by using this rule.

These empirical rules have no obvious scientific justifications. On the other hand, the 'precursor technique' is widely accepted by the scientific community because it has a scientific basis. This technique is based on the concept of extended solar cycles. According to this concept, the true length of a solar cycle is longer than 11 yr (perhaps 18 yr), and a new solar cycle does not start near the end of the preceding solar cycle but starts much earlier in the declining phase of the preceding cycle. Therefore, for some years, two cycles coexist: the signatures of a new cycle are manifested in high latitudes, while sunspots belonging to the declining cycle are found in low latitudes.

According to the precursor technique, each of the geomagnetic indices *Ap* and *aa* is made of two components: one is due to the current-cycle solar activity and the other is due to the precursor of the next solar cycle. The second component is due to stable coronal holes, giving rise to a 27 day recurrent pattern. A stable coronal hole is a unipolar region with magnetic field lines open to interplanetary space. The magnetic fields of unipolar regions are thought to become seeds for the next sunspot cycle. The second component of the geomagnetic indices, therefore, can reveal the strength of the next cycle. On this basis, some solar physicists successfully retrodicted the peak strengths of cycles 12–22. Using this technique, solar physicists formed a consensus that cycle 23 is going to be much stronger than the average.

From the early days of solar activity study, it was attempted to express the sunspot cycle with analytical equations involving a few parameters. Recently, some scientists found that the solar activity curve for each cycle can be fit by a single equation with three free parameters, which are adjustable for each cycle. By fitting such an equation to the rising phase of a sunspot cycle, one can deduce the best values of the free parameters, which in turn determine the activity curve of the remaining part of the cycle. In this method, one has to wait until a new cycle has progressed considerably.

Mid-term forecasting

The prospect of mid-term forecasting of solar activity has not been studied in recent years. Here timescales from months to several years are regarded as mid terms. Scientists and forecasters have not paid much attention

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

to mid-term forecasting because of the lack of useful tools. Recently, it has been found that the occurrence rate of solar flares episodically exhibits periodic modulations. The best-known periodicity is a 152 day periodicity, which was in operation during the four years from 1980 through 1983. Other well-known periods are 51 day and 76 day periods. These periods are close to integral multiples of 25.5 days (2, 3 and 6 times, respectively). Even though these periodicities are not persistent but episodic, it can be used for mid-term flare forecasting when one of them is found to be in operation.

By the end of 1981, one of the scientists in charge of the gamma-ray detector aboard the Solar Maximum Mission found that four episodes of high flare activity were roughly separated by 5 months. Suspecting the existence of 5 month periodicity, he predicted that the next high flare activity would occur in February 1982. Not only was this prediction realized, but also high flare activity was later observed with 5 month intervals (in June and July 1982, December 1982, May 1983 and October 1983). After it was recognized in March 1992 that the 51 day periodicity was in operation, four episodes of high flare activity occurred in accordance with this periodicity. Therefore, one can say that flare periodicities were, in fact, used for mid-term flare forecasting. In order to use flare periodicities as a practical tool for forecasting, however, one has to investigate the reliability and limitation of this method, analyzing the past data.

Short-term forecasting

Studies on flare forecasting have been mostly concentrated in short-term flare forecasting for timescales of a few days. The Space Environmental Lab of the National Oceanic and Atmospheric Administration of the United States of America mainly performs short-term flare forecasts rather than long-term forecasts. All the major flares occur within sunspot groups; hence, the term 'active region' is often used for a sunspot group. Therefore, investigation of the morphology and the development of a sunspot group is a useful tool for making short-term flare prediction. (See SUNSPOT CLASSIFICATION.)

Short-term flare prediction is based on both theoretical understanding of solar flares and hands-on experience of observers. Because a rather small number of highly flare-productive active regions account for the majority of energetic flares, it is important to recognize the signatures of flare-productive active regions. Well-known signatures of flare-productive active regions are as follows.

(i) Complex active regions in which many sunspots of opposite polarities are mixed tend to produce many flares. Even if an active region is made of many sunspots, it is not flare productive if sunspots of one polarity are neatly separated from those of opposite polarity. An active region with a delta configuration, which is defined as two umbrae of different polarities surrounded by a single penumbra, is flare productive.

(ii) If, in a delta configuration, a bright H-alpha plage obscures a part of an umbra or runs along the neutral line, it is very flare productive.

(iii) If an emerging sunspot bumps into an existing sunspot of opposite polarity, flares are likely to occur.

(iv) If magnetic field lines connecting the sunspots of opposite polarities are highly sheared (in other words, the angles between these field lines and the neutral line are small), flares are likely to occur.

(v) A rapidly growing active region is flare productive. In general, an active region in the decaying phase does not produce energetic flares unless new spots emerge within it.

Very-short-term forecasting

Flare prediction with timescales of tens of minutes is based on flare precursors. X-ray bright points, bright EUV knots and high-temperature emission of 6–20 GHz microwaves are recognized as precursors of flares. (See SOLAR FLARES: PREFLARE PHASE.) Such very-short-term flare forecasts are not usually valuable because of short lead times. However, it is useful to recognize early a flare that is likely to be associated with solar energetic particles and/or coronal mass ejections because energetic particles take hours to propagate to Earth and coronal mass ejections take days to do so. Therefore, even if we identify them while they are in progress on the Sun, we can have some preparation time before their impacts arrive here.

Flares associated with large fluxes of solar energetic particles, coronal mass ejections, and interplanetary shocks have been recognized as constituting a distinct class of flares, and they have been called 'proton flares', 'two-ribbon flares', 'gradual flares', 'extended flares', 'long-decay events', 'gradual gamma-ray–proton flares' and so forth. (See SOLAR CORONAL MASS EJECTIONS and SOLAR FLARE CLASSIFICATION.) This kind of flare has several characteristics: (1) long durations (of order of minutes) of individual hard x-ray spike bursts; (2) a long total duration (of tens of minutes) of hard x-ray emission; (3) spectral hardening of hard x-rays during individual spike bursts; (4) a gradual rise and very gradual decay of soft x-ray emission, (5) Two H-alpha ribbons separating gradually. One can use the first three characteristics for forecasting proton flares by analyzing hard x-ray data in real time. Although soft x-ray emission from the Sun is monitored continuously, the fourth characteristic has limited utility because the distribution of soft x-ray emission durations has no recognizable demarcation line. H-alpha observations are routinely available, but H-alpha ribbons begin to separate in the declining phase of a flare, limiting its usefulness as a timely identification method of proton flares.

Future prospects

Identification of flare-productive active regions discussed earlier is mainly based on high-resolution, ground-based observations of magnetic fields and H-alpha emissions of active regions. Now high-resolution instruments aboard

various spacecraft are observing the Sun. The Michelson Doppler Imager (MDI) on the Solar and Heliospheric Observatory is measuring photospheric Doppler shifts with a spatial resolution of 2 arcsec and a good cadence. The Transition Region and Coronal Explorer (TRACE) is observing the transition region and the corona with high spatial resolution. Yohkoh, which has been taking soft x-ray pictures of the Sun since 1991, is still in good condition. When we analyze Yohkoh, MDI and TRACE data appropriately, we may be able to learn new methods of forecasting solar flares.

Using local helioseismology, one can detect sunspots before they emerge to the surface because they absorb p-mode oscillations and modify sound speeds. (See SOLAR INTERIOR: LOCAL HELIOSEISMOLOGY .) This technique has not been perfected yet, but we can see its potential. It is impractical to apply local helioseismology to see whether sunspots are buried below the photosphere at random places and times. However, one can apply this technique to a developing active region to see whether a large reservoir of strong magnetic fields is beneath the surface.

With the abundance of data on solar phenomena recently accumulated and to be obtained in the near future, scientists will be able to better understand various solar phenomena influencing the Earth environment. It will naturally improve the ability to forecast solar flares and space weather in general.

Solar Flare Magnetic Fields

This article describes the relationship between magnetic fields and solar FLARES.

Like most dynamic phenomena on the Sun, the occurrence of solar flares is closely related to the presence and evolution of solar magnetic fields, especially the complicated, non-potential magnetic configuration. As a simple introduction, we compare flares with earthquakes. The occurrence of earthquakes involves two steps: energy build-up and energy release. The stress and energy are built up by relative motion of two tectonic plates along fault lines. When the stress reaches a critical point, two plates cannot slide further, the equilibrium breaks down and a section of the fault line is restored to its original position (minimum energy state). The excess energy is released in the form of kinetic energy and propagated as seismic waves. A simple flare can be described by a very similar scenario. We start with two magnetic regions of opposite polarities. The line dividing two polarities is called the neutral line. If the field lines are connected directly, i.e. perpendicular to the magnetic neutral line, this is called the potential configuration. If, for some reason, magnetic regions slide, the field lines will start to move away from perpendicular to the neutral line. This is called the sheared configuration. In an extremely sheared configuration, the magnetic field lines are nearly parallel to the neutral line. A sheared magnetic field has more magnetic energy than the corresponding potential field configuration and the extra energy is called the free magnetic energy. When the fields are extremely sheared, an instability occurs. Fields tend to be restored to the potential configuration and magnetic free energy is released by the process of MAGNETIC RECONNECTION. The free magnetic energy is converted to thermal and non-thermal energy to power solar flares, which create thermal emissions and acceleration of non-thermal particles. The total energy of a flare depends on the total volume and complexity of the sheared magnetic region.

The determination of the magnetic field configuration in flare-productive regions can be done directly and indirectly. Most of the methods will be addressed throughout the article. Here is the summary of them. The most direct way is by the vector magnetograph observations, at present all from ground-based solar observatories. However, the Japanese–US mission SOLAR-B (launch date: 2004) will provide the first space measurements of this kind. The line-of-sight magnetograms can provide certain information of ACTIVE REGION magnetic structure too: data are available from space (e.g. MDI on board SOHO) as well as ground-based observatories. Indirect measurements of magnetic field structure include Hα, white-light and D3 images from ground-based observations and soft X-RAY (YOHKOH), UV/EUV (TRACE, EIT/SOHO) images from space observations.

In addition to the presence of sheared magnetic neutral lines, the complexity of active regions is also vitally important in producing solar flares. The close association between δ sunspots and major solar flares provides evidence that flares are associated with complexity of active regions (Zirin and Liggett 1987). The δ sunspots are SUNSPOTS having two or more umbrae of opposite polarities within a common penumbra. Figure 1 shows an example of a δ sunspot. It is a magnetogram of active region NOAA 6659, taken on 10 June 1991 by Big Bear Solar Observatory; white and black gray scales represent line-of-sight magnetic field of north and south polarities respectively. The dominant negative spots are surrounded by opposite-polarity satellite spots. This active region was one of the most flare-productive regions in solar cycle 22, which produced many flares including six of the strongest flares (classified as X-class flares). As a matter of fact, almost all of the more than 100 X-class solar flares that occurred in solar cycle 22 were associated with δ sunspots.

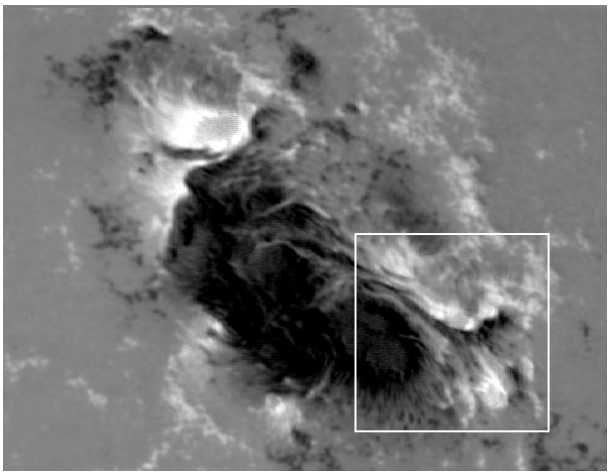

Figure 1. A line-of-sight magnetogram of 10 June 1991 active region NOAA 6659 obtained at Big Bear Solar Observatory. It is a δ sunspot group. The field of view is 5 arcmin $\times$ 4 arcmin. White and black gray scales represent field strength of positive and negative magnetic polarities, respectively. The dominant negative spots are surrounded by opposite-polarity satellite spots. In the lower-right corner (marked by a white box), a magnetic channel structure due to new flux emergence is visible.

Another prominent common feature in the flare-productive δ sunspot groups is the unbalanced magnetic flux inside the δ configuration. Again, figure 1 gives a very good example of an unbalanced magnetic flux configuration. Inside the δ group, the negative magnetic flux (field strength multiplied by area) is about 6 times greater than the positive flux. From theory, of course, we know that the overall fluxes must be balanced when added up over a large enough area. It is not clear why the flare-productive δ groups always show such very unbalanced fluxes. Statistical studies show that the average ratio of dominant flux versus minor flux is around 5 in all the δ groups.

Another very important aspect in flare magnetic field studies is the electric currents in flare-producing regions.

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

When the field is potential, it is called the current free field. Sheared and twisted magnetic fields carry electric currents. The existence of currents is important for flares, because an electric field is most efficient in both heating (Joulean dissipation) and acceleration of charged particles.

The magnetic fields in flare-productive active regions have been observed by various vector magnetograph systems. The most notable ones are systems at Marshall Space Flight Center, Big Bear Solar Observatory, Huairou Solar Observatory, Mees Solar Observatory and Advanced Stokes Polarimeter at National Solar Observatory. Studies of the magnetic structure of flare-producing regions have been concentrated in the following areas.

Relationship between magnetic shear and solar flares

Study on this subject was first carried out extensively by the solar group at Marshall Space Flight Center/NASA. The magnetic shear is defined as the angular difference between the azimuth of the potential transverse field calculated from the observed longitudinal magnetic field and the observed transverse magnetic field (Hagyard *et al* 1984). Statistically speaking, flares occur in areas where the local photospheric magnetic field departs the most from a potential field. These regions are characterized by (1) high shear angle, (2) strong transverse magnetic field along the neutral line and (3) long sheared magnetic neutral line. Figure 2 shows a transverse magnetogram of 10 June 1991, obtained at Marshall Space Flight Center. It contains the top-left part of the active region shown in figure 1. Magnetic neutral lines are shown as contours and the transverse fields are represented as bars. These field components are superposed on a broad-band Hα image which shows that the flare kernels were on opposite sides of the neutral line in an area where the transverse field was highly sheared along that line.

However, more recently, it has been found that not all the flares occur in sheared neutral lines. If the flare ribbons start near the neutral line, the strong shear conditions are usually satisfied. If the flare ribbons start further apart, the neutral line may not have large shear (Chen *et al* 1994). The former situation may represent a reconnection closer to the photosphere, while the latter may imply a reconnection higher up.

Flux emergence and formation of magnetic shear

The picture of magnetic shear due to relative motion of magnetic regions that we gave in the introduction is oversimplified. There are several ways that a sheared magnetic configuration can form. A few examples are given here and have been discussed by Wang (1993, 1997): (a) shear formed by relative shear motion of magnetic regions with opposite polarities; (b) shear formed by head-on collision between two magnetic regions of opposite polarities; (c) complicated magnetic structure, perhaps formed as a result of new flux emergence, in which opposite magnetic polarities can be closely intertwined. The three most famous superactive regions in solar cycle 22 (NOAA 5395, March 1989; NOAA 6659, June 1991; NOAA 6891, October 1991) all show very similar new flux emergence inside the already existing penumbrae, and new fluxes subsequently formed magnetic channels (elongated mixed-polarity magnetic regions) with high magnetic shears. These new flux emergence regions are the sites of many major solar flares (see CHROMOSPHERE: EMERGING FLUX REGIONS). In the lower-right part of figure 1 (marked by a box), the magnetic channel structure is demonstrated for the June 1991 region, which was a result of new flux emergence inside the sunspot penumbra.

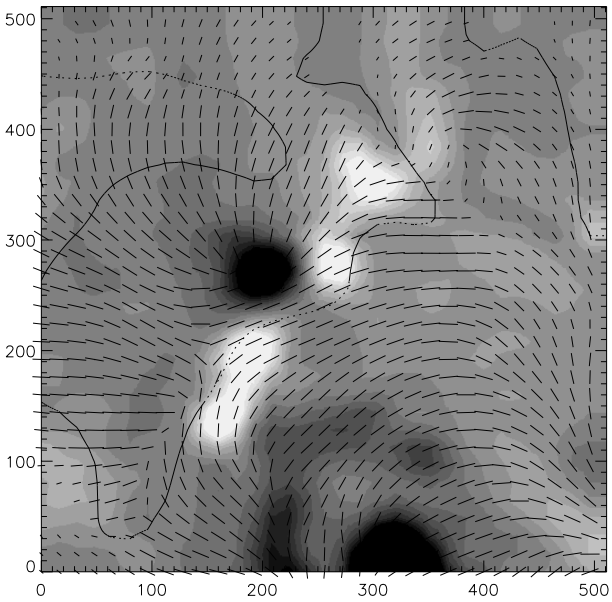

Figure 2. AR6659 on 10 June 1991, at the start of an M3 flare at 16:53 UT. The 1.5 arcmin square field of view shows the north-east portion (top-left) of the same active region as in Figure 1. The solid contour marks the magnetic neutral line separating the positive polarity of the umbra near the center of the picture from the negative polarity of the larger umbra at the bottom. The line segments indicate the magnitude and direction of the transverse component of the magnetic field and are scaled from 125 to 500 G. These field components are superposed on a broad-band Hα image which shows that the flare kernels were on opposite sides of the neutral line in an area where the transverse field was highly sheared along that line. This figure is provided by Dr M Hagyard at Marshall Space Flight Center.

It has also been brought to light that magnetic shears may not be caused by surface flows; they may instead be formed beneath the surface by convective motion. When flux emerges, the twisted flux tubes are brought up above the surface, which provides free energy to power flares. Such an idea was originally proposed by Tanaka (1991) based on observations from Big Bear Solar Observatory. In a recent paper, Ishii *et al* (1998) studied active region 5395 (March 1989) in detail. To explain the apparent complicated flux emergence and flow motions, they proposed a schematic model of the successive emergence of twisted and winding magnetic flux ropes coiling around a trunk of a big magnetic

flux tube. The location of strongest flare activity was found to coincide with the vortex-like apparent surface motion of sunspots which are actually a consequence of twisted flux emergence. Data obtained with the Advanced Stokes Polarimeter confirmed such an idea of emergence of twisted flux tubes (Lites and Low, 1997).

Changes of magnetic shear after solar flares

Before vector magnetograms were available, people used the Hα fibril structure to study the shear of magnetic fields and its relation to flares. Sheared magnetic neutral lines can be easily visible as filaments which are dark elongated structures in the solar chromosphere, as seen in Hα images. Evidence exists to show that the field lines are along the major axis of filaments—in the same direction as neutral lines. Many flares are related to eruptions of filaments. Eruptive filaments are also known to be associated with a type of large-scale coronal activity called coronal mass ejections. Relaxation from a sheared to a potential magnetic configuration is evidenced by the disappearance of sheared filaments and formation of potential post-flare loops which connect two magnetic polarities directly (Zirin 1988). However, the Hα structure may only represent the field in the chromosphere. Although in some cases it matches the direction of the transverse field in the photosphere, it is not guaranteed that this match is still valid for complex flare-producing regions. Furthermore, Hα fibrils provide only the direction; transverse field measurements provide field strength as well. X-ray loop structures and their evolution during flares, as observed by the Japanese Satellite Yohkoh, have demonstrated magnetic reconnection and the change from a sheared to a more potential configuration. However, studies of the evolution of photospheric magnetic fields in flare-producing active regions is still very important, because they are the only way to provide a quantitative description of magnetic fields in active regions. Even though observed fields are measured along a two-dimensional surface, force-free magnetic field extrapolations based on measured photospheric magnetic fields as a boundary condition provide a powerful tool to obtain the three-dimensional field structure.

Study of evolution of vector magnetic fields during solar flares requires accurate vector field measurements, with sufficient spatial resolution (1–2 arcsec, the solar diameter is about 2000 arcsec), high cadence (5 min or less) and long duration (several hours before and after flares). Only sufficiently strong flares may have a measurable effect on photospheric magnetic fields. Giving the observing requirements, it is not surprising that such observing sequences are rare. At the time of writing, the change of photospheric magnetic fields before and after solar flares is still an unsettled issue. Wang (1997) has reported shear increases for five X-class flares, while Chen *et al* (1994) reported that there were no detectable changes associated with about 20 M-class flares. Observations at Marshall Space Flight Center demonstrated a similar inconsistency: some events show a shear increase, some a decrease and some were unchanged. Theoretical predictions are also mixed, as shear increase, decrease or undetectable changes in photospheric magnetic fields can each be explained by different models. Flares are mainly considered as coronal events; in the corona, the magnetic shear has to be released to produce solar flares, so shear there is definitely released after a flare. It may not be required for its photospheric boundary to have similar shear relaxation.

The study of magnetic fields in flare-productive regions is still a very active research area. The most outstanding problems include the following. (1) How is magnetic shear built below or above the surface? (2) Do photospheric magnetic fields change when flares occur mainly in the chromosphere and corona? (3) Can we observe direct evidence of magnetic reconnection as a result of flares? To answer these questions, a new generation of instruments and new models are needed. New observations would require high spatial and temporal resolutions as well as accuracy in the polarization measurements. They also need to be multiwavelength so information from the photosphere to corona can be combined to provide a three-dimensional view of this physical problem. Observations from new space missions such as TRACE and planned missions such as Solar-B and improved ground-based instruments such as SOLIS may shed light on this research area.

Solar Flare Models

Even though FLARES have been observed on the Sun for nearly 150 years, their origin remains a mystery. At the present time there is no generally accepted model which explains why they occur, but there do exist models which successfully explain certain limited aspects such as the formation of flare loops and ribbons. Before discussing particular models, we review the constraints imposed on models by the observed properties of flares.

Principal observational constraints

In constructing models, theorists are constrained by several basic properties of flares which have been firmly established by observations (see also SOLAR FLARE OBSERVATIONS). One of the most important is that they occur in a PLASMA environment dominated by magnetic fields. Magnetic energy is the only source of energy in the solar atmosphere which is capable of producing the radiative and kinetic energy output of large flares. Prior to the onset of a flare the magnetic energy density ($B^2/2\mu_0$, where μ_0 is the permeability of free space) of a 100 G (10^{-2} T) coronal field is about 40 J m^{-3}. By comparison, the thermal energy density (nkT, where k is Boltzman's constant) is about 0.01 J m^{-3} since the coronal particle density, n, and temperature, T, are about 10^{15} m^{-3} and 10^{-6} K respectively. Finally, the kinetic energy density ($m_p n v^2/2$, where m_p is the proton rest mass) in the corona is about 10^6 J m^{-3} assuming that the velocity, v, is of the order of 1 km s^{-1}—the convective velocity imparted by flows at the photospheric level. The gravitational energy density ($m_p n g h$, where g is the solar surface gravity of 247 m s^{-2}) is of the order of 0.04 J m^{-3} assuming that the average mass height, h, is about 10^8 m. Thus, the magnetic energy density is about three orders of magnitude greater than any of the other types. Since large flares typically have an energy of 10^{25} J (10^{32} erg) and a volume in the range from 10^{24} m^3 to 10^{25} m^3, an average energy density of 1–10 J m^{-3} is required. Only the magnetic energy density is in this range, so non-magnetic models of flares are ruled out.

Another important constraint is that the slow movements of SUNSPOTS and other magnetic features in the SOLAR PHOTOSPHERE are unaffected by the occurrence of flares. This is because the plasma in the photosphere is almost 10^9 times denser than the plasma in the corona where flares originate. Consequently, it is very difficult for disturbances in the tenuous corona to affect the extremely massive plasma of the photospheric layer. Field lines mapping from the corona to the photosphere are said to be 'line-tied' to the photosphere, meaning that the footpoints of coronal field lines are effectively stationary over the timescale of a flare.

Perhaps the most important observational constraint is the rapid timescale of the initial flare development. From observations it has been estimated that as much as 10^{25} J (10^{32} erg) is generated in the form of thermal and kinetic energy during the first few minutes after onset. This is an extremely short timescale for an organized process to be occurring over a region whose size is of the order of 10^5 km (about 10 times larger than the diameter of the Earth), and it implies dynamic velocities of the order of 100–1000 km s^{-1}—close to the speed at which magnetic and acoustic waves propagate in the corona. The implication of such a large energy output in so short a time is that about 10% of the available magnetic energy in a volume of 10^{15} km^3 is converted to thermal and kinetic energy within a few wave-travel times. In other words, flares require a process which converts magnetic energy with an efficiency of the order of 10%, or greater, on a timescale which is only a few times greater than the wave travel time. This combination of efficiency and speed is not easy to explain theoretically.

There are some additional constraints that are especially important for the class of flares known as large, two-ribbon flares or long duration events (see SOLAR FLARE CLASSIFICATION). After the initial rapid phase, these flares continue to produce a sustained, low level emission for over 10 h. They stand in stark contrast to the more numerous, short-lived events (<30 min), known as compact flares. Long duration events give rise to two bands of chromospheric emissions called flare ribbons which slowly propagate away from one another. (Compact flares may also produce ribbons which are usually called 'knots' because they are small and short-lived.) The flare ribbons lie at the feet of dense, x-ray emitting loops often referred to as 'post'-flare loops with the word 'post' in quotes to indicate that nowadays they are considered an integral part of the flare process, rather than simply an aftereffect. High resolution images and Doppler measurements have established that the motion of both ribbons and loops are only apparent and are caused by the progressive lighting up and dimming of the regions through which they propagate. Models for large, two-ribbon flares must be able to account for these apparent motions as well as the long lifetime of the events themselves.

Difficulties of constructing flare models

It is sometimes thought that the only requirement for a successful theoretical model is that its predictions match observations. What is forgotten in this simplistic view is that any model can be made to match a particular set of observations to any degree of accuracy desired simply by including enough adjustable, free parameters. When the number of free parameters reaches the point where there is one for each observational measurement, the model becomes simply a reorganization of the observational data. Thus a successful model should not only match observations, but also have as few free parameters as possible.

Virtually all quantitative flare models are formulated as solutions of initial boundary-value problems. These problems are comprised of a system of differential equations, a set of boundary conditions, and an initial state. Since the underlying system of differential equations for all models are those of electromagnetism (i.e. Maxwell's

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

equations) and Newtonian mechanics (for continuous media), models differ from one another in their choice of boundary and initial conditions and in the approximations which are made to solve the equations.

Most flare models use the MAGNETOHYDRODYNAMIC (MHD) approximation. Although these equations do not provide a description of kinetic processes, they nevertheless provide a complete and self-consistent description of the fluid behavior of the coronal plasma, and what is equally important, they can be solved in many circumstances where more complete descriptions cannot. Used alone, the MHD equations do not provide any information on the production of radio waves or energetic particles, both of which constitute a major database for the flare phenomenon. Thus, several flare models attempt to augment the MHD system by adding additional equations. For example, some energetic particle models use an MHD solution to provide electric and magnetic fields as inputs into the exact equation which describes the motion of the particles in electromagnetic fields (i.e. the Lorentz force equation).

Boundary conditions for flare models are fairly well constrained by observations. Observations have already established that ACTIVE REGIONS, with complex magnetic fields, are most likely to flare. Particularly favored are active regions containing multiple sunspots with opposite magnetic polarities in close proximity to one another and undergoing motions which act to shear the magnetic field. These observations imply that currents are built up in the corona prior to a flare by the transport of magnetic flux from the convection zone into the corona and by the stresses exerted on the existing coronal field by the shear flows in the photosphere.

The greatest uncertainty in the development of quantitative flare models is caused, not by the boundary conditions, but by the initial conditions because these are very poorly constrained by observations. Since the flare is a magnetic phenomenon, the magnetic vector field is the most important variable which needs to be specified in the initial state. Unfortunately, the magnetic field is the one quantity which cannot be directly observed in the corona at the present time. The problem of determining the coronal magnetic field is further exacerbated by the fact that it is only the component of the magnetic field generated by currents flowing in the corona that contributes to the energy release. The component of the field due to photospheric sources remains invariant during a flare and so cannot contribute to the energy release. The contribution to the magnetic field from the coronal currents is estimated to be anywhere between 10–50% of the total field. Thus, even if the coronal magnetic field could be directly observed, it would be necessary to measure its strength and its orientation to an accuracy of about 10% everywhere in the flare region before such measurements could be used to formulate initial conditions. The best that can be done at the present time is to infer the coronal magnetic structure from variations in the density and temperature of the coronal plasma. This is done by assuming that such variations occur only across field lines, so that contours of constant density or temperature follow field lines. However, there are many instances where this assumption is known to be violated (e.g. density and temperature structures in flare loops).

Even if the system of equations, the boundary conditions, and the initial conditions could be accurately established by observations, there would still be the enormous mathematical difficulty of actually solving the governing equations. Fluid equations, with or without the addition of Maxwell's equations, are notoriously difficult to solve because of their high degree of nonlinearity. For example, there is still no generally accepted analytical description for ordinary fluid turbulence, let alone MHD turbulence. Some progress has been made using numerical methods, but these methods cannot handle the tremendous range of scales involved in flares. To provide a complete description of all phenomena, a flare model should include scales as small as 10^{-2} m (e.g. an electron gyro radius) and as large as 10^{8} m (or even greater) if the flare produces a SOLAR CORONAL MASS EJECTION.

Most modelers, whether they use analytical or numerical techniques, are forced to simplify the geometry of their initial configuration to the point where it is far removed from the complexity of the actual solar field. However, such models are still valuable because they provide a quantitative way to test whether a proposed flare mechanism is really consistent with the laws of physics. It will be many years before it is technically possible to solve the complete set of plasma equations using initial and boundary conditions which actually match reality.

Storage models

Most flare models are based on mechanisms which release magnetic energy stored in the corona. The energy is stored in the form of coronal currents, and it is released when these currents become unstable due to the slow evolution of the normal magnetic field component at the photosphere. The continual emergence of new flux from the convection zone and the shuffling of the footpoints of closed coronal field lines causes stresses to build up in the coronal field. Eventually, the stress exceeds a threshold beyond which a stable equilibrium cannot be maintained, and the field undergoes a rapid transition to a configuration with a lower magnetic energy.

Because the magnetic pressure greatly exceeds the gas pressure in the corona, the currents associated with the magnetic energy stored there must either be force-free (i.e. field aligned) or confined to thin layers (i.e. current sheets). In other words, the energy cannot be stored as a distributed, non-force-free current since such a current cannot be in equilibrium in the absence of any significant gas pressure. Models for magnetic energy storage in the corona can be divided into those based on force-free currents and those based on current sheets. A well-known example of the latter is the emerging flux model illustrated in figure 1. As new flux emerges from the photosphere it

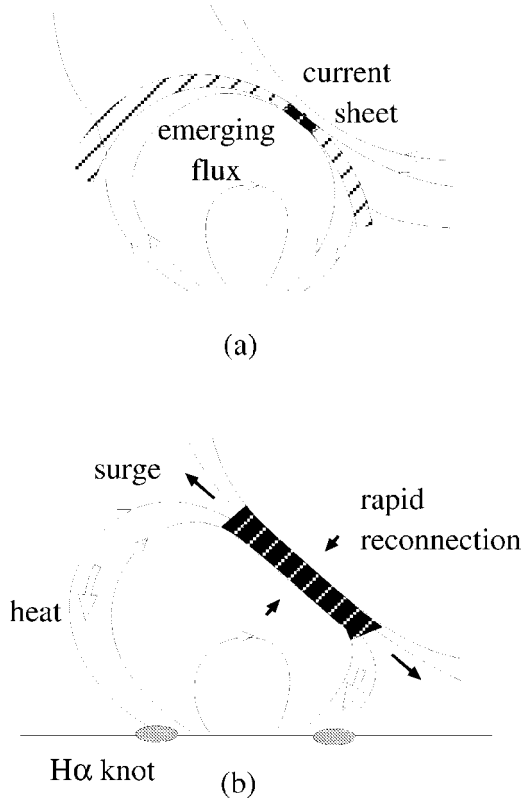

Figure 1. The emerging flux model of impulsive flares. In (a) a current sheet forms as a newly emerging loop collides with a pre-existing field. In (b) the onset of a resistive microinstability produces rapid reconnection of the field lines.

forms a current sheet as it presses against field structures that are already present. As the current in the sheet grows, it may then reach a critical threshold for the onset of a micro-instability. Once such an instability occurs, it is possible that the local resistivity of the plasma will increase so much that the current sheet is rapidly dissipated by means of magnetic reconnection. This process changes the connectivity of the field lines and releases most of the stored magnetic energy, but in order to be effective in flares it must occur very rapidly. How such rapid reconnection occurs is still a matter of debate.

In order for the emerging flux model to work for large flares, the pre-existing current sheet must be stable for a period of the order of a day or more. However, numerical simulations suggest that coronal current sheets reconnect so rapidly that a stable sheet cannot be sustained for such a long period of time. The success of x-ray bright-point models, which assume that current sheets are dissipated as soon as they try to form, reinforces this view (see SOLAR CORONA: X-RAY BRIGHT POINTS). Also, since no flux is ejected in the emerging flux model, it cannot explain the coronal mass ejections that are associated with very large flares. Thus, the emerging flux model is limited to small flares.

One type of force-free model that has received much attention is based on trying to create an eruption by shearing the footpoints of an arcade of loops. In two-dimensional force-free configurations with translation symmetry (i.e. sometimes referred to as $2\frac{1}{2}$ D configurations) shearing causes the arcade to smoothly expand outwards towards a fully opened state without ever producing an eruption. It is not yet known for certain whether an arcade will maintain a stable equilibrium as its footpoints are sheared in less symmetric systems. Even if no loss of mechanical equilibrium or stability occurs, it is still possible to create an eruption of the arcade by invoking a resistive instability as is done in the emerging flux model. Shearing an arcade leads to the formation of a current sheet which can undergo reconnection, but again there must exist a critical threshold for the sudden onset of a micro-instability.

Another way for an arcade to form is for part of a flux rope to emerge from the convection zone, through the photosphere and into the corona. If the axis of the flux rope remains below the surface, then a simple arcade exists. However, if the axis of the flux rope emerges into the corona, the arcade will contain a flux rope. The presence of the flux rope may make it possible for the arcade to lose equilibrium and erupt even when no current sheet or x line is present.

Figure 2 shows a quantitative flux-rope model which demonstrates the underlying principle of this process. The model has the drawback that it is two dimensional and, therefore, does not include the effect of anchoring the end of the flux ropes in the photosphere. The evolution of the configuration takes place in two phases. During the storage phase, the evolution is assumed to be slow relative to all other timescales, so that at any given moment the configuration is very well approximated by a static equilibrium. The second phase occurs when the sources reach a critical distance, which is of the order of the initial height of the flux rope. At this point the equilibrium vanishes, and the flux rope jumps to a higher altitude. This process releases a small fraction ($\approx$5%) of the magnetic energy stored in the system, and creates a large-scale current sheet as shown. The extent and lifetime of this current sheet depends on how fast reconnection occurs. Without reconnection, there is no further release of energy, and the jump of the flux rope is finite, but if reconnection occurs, the flux rope can continue to move upwards indefinitely.

At least two important issues still remain to be investigated before the viability of flux-rope models can be satisfactorily determined. First of all, there is the unknown effect of anchoring the ends of the flux rope in the photosphere. Although anchoring the ends might make an eruption more difficult, it is not clear that it would prevent a loss of equilibrium from occurring. The motion of the middle of the flux rope relative to the ends would constitute a type of external kink, and it is known that kink modes are not stabilized by anchoring the ends of a flux rope if the rope is sufficiently long. Second, there is the question of whether the two-dimensional flux-rope equilibria will remain stable to the kink instability as the system approaches the equilibrium point.

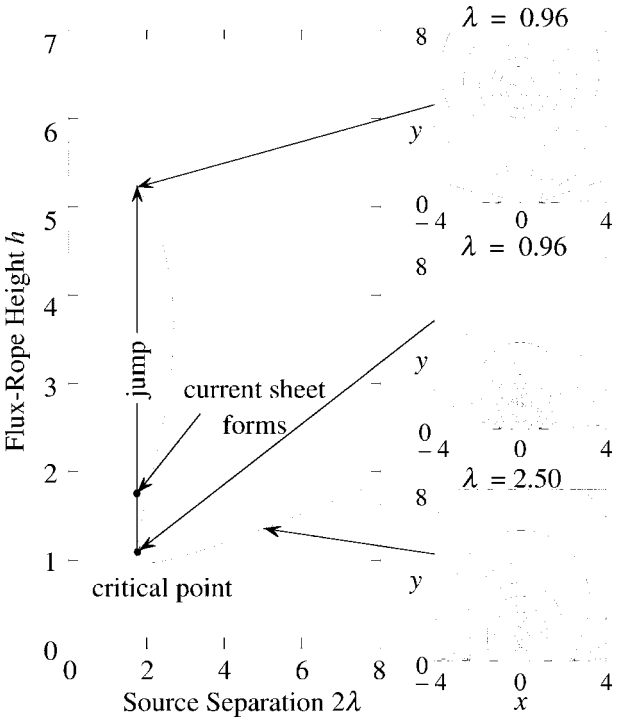

Figure 2. An arcade model containing a flux rope. Eruption occurs when the source regions in the photosphere are pushed together. A current sheet forms only after the eruption begins.

Models for flare loops and ribbons

Flare loops range from temperatures of 10^4 K to 3×10^7 K with the cooler loops nested below the hotter ones. Remarkably, the loops at the low temperature are two orders of magnitude cooler than the ambient coronal plasma even though they lie underneath a region which is an order of magnitude hotter than the ambient corona. It is generally accepted that the cool loops are formed from the hot loops by a thermal instability. Such an instability is possible in the solar atmosphere because of the non-black-body behavior of the corona. The coronal radiative loss function decreases with temperature in the range from 10^5 K to 10^7 K, so in this range a temperature perturbation can lead to runaway cooling.

The footpoints of the flare loops map to Hα emission features in the CHROMOSPHERE that are known as flare ribbons. (Hα refers to the red light emitted in the Balmer transition of the hydrogen atom.) Very roughly, the outermost edge of the hot x-ray loops maps to the outer edge of the ribbons while the innermost edge of the cool Hα loops maps to the inner edge of the ribbons. During the course of the flare the separation between the ribbons increases, while the loops grow larger.

At the present time, MAGNETIC RECONNECTION is thought to be the only mechanism which can account for the apparent motion of the flare loops and ribbons. Although some alternate mechanisms have been suggested in the past, these mechanisms have become less tenable as observations have improved. For example, simple expansion of the loops due to outward motion of the plasma from the flare site has been ruled out by Doppler-shift measurements of Hα loops. These measurements show that the plasma in the Hα loops flows downward at speeds of 100–500 km s^{-1} during the time that the loops appear to be expanding upwards. Thus the loop motions are not due to mass motions of the plasma, but rather to the continual propagation of an energy source onto new field lines.

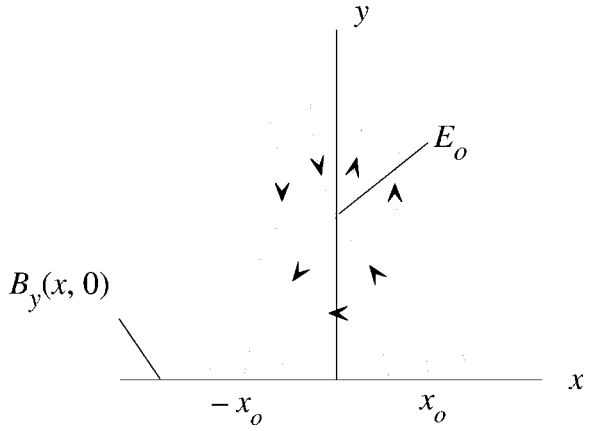

Figure 3. Relation between the rate of reconnection, as measured by the electric field at an x line, and the motion of the flare ribbons.

In a two-dimensional configuration there is a simple relation between the rate of reconnection and the motion of the photospheric footpoints of the field lines mapping to the x line. Consider the configuration shown in figure 3. Using Faraday's equation, the electric field E_0, at the x line can be written as

$$E_0 = V_0 B_y(x_0, 0) \tag{1}$$

where x_0 is the location of the outer edge of the ribbon, $B_y(x_0, 0)$ is the vertical magnetic field located at x_0, and V_0 is the apparent velocity of the ribbon edge. This relation is model independent except for the assumptions that an x line exists, that the configuration is two dimensional, and that the field lines are tied to a stationary photosphere.

If one assumes that the outer edges of the flare ribbons lie at the footpoints of the field lines mapping to the x line, then it is possible to use equation (1) to determine the electric field in the corona as a function of time, as shown in figure 4 for a flare observed by the SKYLAB space station in 29 July 1973. A few minutes after flare onset the electric field for this event reaches a peak value of about 2 V cm^{-1}, but then declines until it is an order of magnitude weaker a few hours later.

Although one can argue that the loop and ribbon motions are strong evidence of reconnection , they are, nevertheless, indirect evidence. In principle, x-ray observations of sufficient spatial resolution and sensitivity can provide direct evidence. However, the ability to

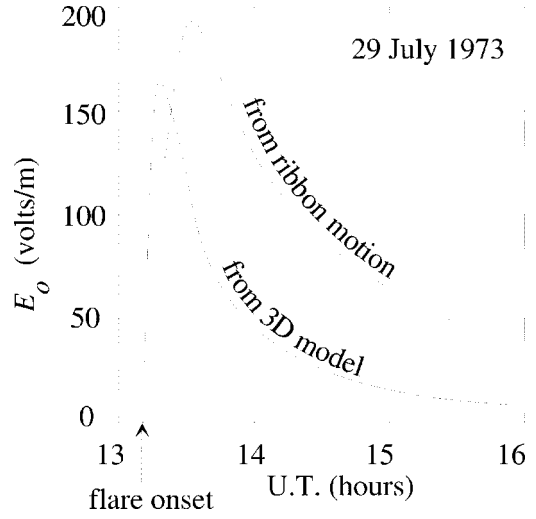

Figure 4. Coronal electric field inferred for the flare on 29 July 1973. The upper curve is obtained using formula (1) in the text, while the lower curve is based on a more elaborate three-dimensional potential extrapolation of the surface field.

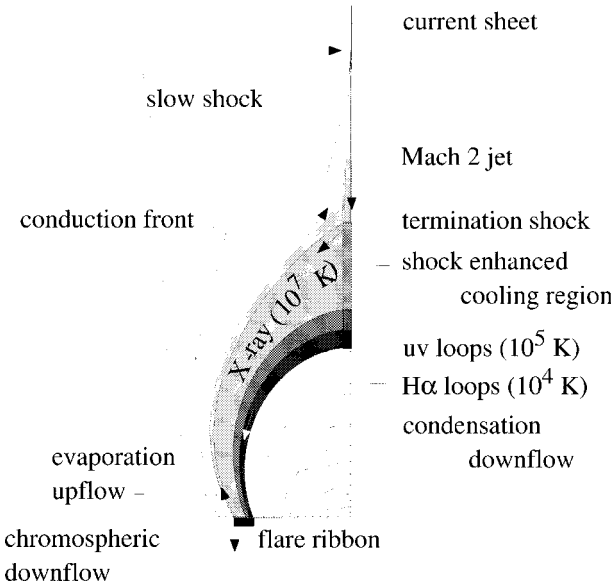

Figure 5. Model diagram for a flare loop system formed by reconnection in the corona (only the left half is shown). In this particular model, the outflow from the reconnection region creates upward and downward supermagnetosonic jets, but only the downward jet is shown in the figure. Solid curves indicate boundaries between various plasma regions, while dashed ones indicate magnetic field lines.

determine whether or not there is a reconnection site in the corona depends very much on theoretical expectations of what such a site should look like. High resolution images obtained from x-ray telescopes on the Japanese satellite YOHKOH show several features that are suggestive of a reconnection site in the corona. These features include: (i) a hard x-ray source located above the soft x-ray loops; (ii) cusp structures suggestive of either an x type or a y type neutral line; (iii) bright features at the top of the soft x-ray loops; and (iv) high temperature plasma along the field lines mapping to the tip of the cusp.

Some of the cusp-shaped loops observed by Yohkoh have a linear, trunk-like feature which extends from the top of the cusp all the way down to the innermost arch of the flare loop system. The hottest regions in the loop system do not lie in the trunk feature but along the edges of the cusp formed by the outermost loop. The trunk feature is both cooler and denser than the plasma surrounding it.

Figure 5 shows a theoretical model which explains the loop structures and evolution in terms of reconnection and evaporation. According to this model, flare loops are created by chromospheric evaporation on field lines mapping to slow-mode shocks in the vicinity of the neutral line (sometimes referred to as Petschek shocks). These slow shocks are somewhat different than the standard MHD slow-mode shocks because the conduction of heat along the field lines causes them to dissociate into isothermal subshocks and conduction fronts. The shocks annihilate the magnetic field in the plasma flowing through them, and the thermal energy which is thus liberated is conducted along the field to the chromosphere. This in turn drives an upward flow of dense, heated plasma back towards the shocks, and compresses the lower regions of the chromosphere downward.

In order for strong slow shocks to form on the field lines below the X-line, the outflow from it must be supermagnetosonic with respect to the fast-mode wave speed. If the magnetic fields are sufficiently strong, the outflow from the X-line produces two supermagnetosonic jets—one directed upward and the other downward. Because of the obstacle presented by the closed field lines attached to the photosphere, the lower jet terminates at a fast-mode shock after traveling a short distance. Below this termination shock the flow is deflected along the field, and only weak, field aligned slow-mode shocks are present. Consequently, the magnetic energy released below the termination shock is relatively small.

When the magnetic field is relatively strong, the fast-mode Mach number of the jets is about two, but as the field decreases, the Mach number decreases and the jets eventually become submagnetosonic. The transition occurs when the ratio of gas to magnetic pressure (plasma β) exceeds $(3-\gamma)/\gamma$ in the x-ray loops where γ is the ratio of specific heats. For $\gamma = \frac{5}{3}$ this gives $\beta = \frac{4}{5}$, which for typical loop parameters corresponds to a coronal magnetic field strength of a few gauss.

When the fast-mode Mach number becomes less than one, the lower jet disappears and almost all of the outflow from the neutral line is directed upwards. Only a relatively slow flow, aligned along the separatrices, remains below the neutral line. An upward reconnection jet is still present, but it is located at the upper end of a current sheet which may extend far out into the corona. Slow

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

shocks are still present below the neutral line at the lower tip of the current sheet, but they are aligned along the separatrices and are much weaker than the Petschek-type shocks. Because of the weaker shocks, the evaporation process is greatly reduced and the plasma density in the loops becomes too low to trigger a thermal condensation. For a while, condensations remain on the loops at lower altitude, but, eventually, as the older loops continue to cool and disappear, the trunk feature vanishes.

The ribbon width, W, is approximately determined by

$$W = V_0 t_{\rm cr} \tag{2}$$

where V_0 is the ribbon velocity and $t_{\rm cr}$ is the cooling time due to conduction and radiation acting together. For the 29 July 1973 flare observed by Skylab, the observed densities and temperatures imply cooling times ranging from $t_{\rm cr} = 15$ min ($n = 10^{17}$ m^{-3}) shortly after flare onset to $t_{\rm cr} = 240$ min ($n = 10^{16}$ m^{-3}) 10 h after onset. When used in equation (2), these values predict ribbon widths which agree well with the observed widths.

The thickness, $W_{\rm j}$, of the region of the ribbon which maps to the reconnection jet, is roughly

$$W_{\rm j} = (V_{\rm R}/V_{\rm j}) L_{\rm j}$$

where $V_{\rm j}$ is the speed of the plasma flow in the jet. Assuming $V_{\rm j} = 10^3$ km s^{-1}, $V_{\rm R} = 10$ km s^{-1}, and $L_{\rm j} = 10^5$ km, gives $W_{\rm j} = 10^3$ km which is a little more than an arcsecond in angular size. This value of $W_{\rm j}$ is consistent with the dimensions of the thin ($\approx 1''$) region of redshifted chromospheric plasma observed at the outer edge of flare ribbons. The redshift is thought to be produced by the bombardment of the chromosphere by energetic particles produced in the region of the jet.

One possible explanation for the lower part of the trunk feature is that it is created by the onset of the thermal instability which produces the cool Hα loops lower down. A very similar feature has been found in numerical simulations which include radiation but not conduction. In these simulations the termination shock triggers a thermal instability in the downstream region, and as the reconnection site travels upward, the condensing region forms a trunk-like feature on the static loops.

Just as for reconnection in the geomagnetic tail (see MAGNETOSPHERE OF EARTH: GEOMAGNETIC TAIL), reconnection in flare loops leads to a relaxation of stretched field lines. In the geomagnetic tail, this relaxation is referred to as dipolarization, but in flare loops it is referred to as shrinkage. What causes the shrinkage is the upward retreat of the neutral line. When a field line is connected to the neutral line it is cusp-shaped, but as the neutral line moves further up, the field line becomes rounded. The expected shrinkage from this effect is about 20–30% for typical flare loops, and this matches the observed values fairly closely.

Solar Flare Observations

Flares are caused by the release of magnetic energy up to some 10^{27} J in the solar atmosphere within a few minutes (figure 1). The energy input causes a myriad of phenomena including the flaring up of the region and its surroundings at all wavelengths from radio to gamma rays, the acceleration of elementary particles to relativistic energies and the launch of a shock wave. Flares may be responsible for the heating of the solar corona and for large-scale restructuring of the corona. The largest ones influence interplanetary space and substantially affect the Earth's lower ionosphere. Solar flares have been a major, unexplained problem of astrophysics for more than a hundred years.

History of solar flare observations

The history of flare observations is a fascinating unfolding of a persisting enigma and is full of surprises. The first solar flare was recorded independently by R C CARRINGTON and R Hodgson on 1 September 1859. They recognized intensely bright patches close to a group of dark sunspots. In retrospect the patches can be identified as a white light flare of the photospheric continuum emission, consistent with the great, terrestrial magnetic storm that occurred a few hours later. With the visual technique at that time, flares were extremely rare phenomena. That changed a few years later with the newly developed spectroscope. C A Young, C Secchi and J N LOCKYER noted much more frequent brightenings near sunspots in certain spectral lines, particularly in the hydrogen Hα line originating at a higher altitude, in the chromosphere. G E HALE's spectrohelioscope made this method sensitive enough in the early 1930s to record several such Hα flares per active day.

The gradual progress in observations and understanding changed pace in 1944, when J S HEY serendipitously discovered solar radio emissions and associated some of them with flares. At about the same time, S E Forbush noticed ground-level cosmic ray enhancements associated with major solar flares. These discoveries could only mean that the flare phenomenon is not confined to thermal plasma, but includes high-energy particles and involves the corona. Rocket flights in 1959 by T A Chubb, H FRIEDMAN and R W Krepin detected flare x-rays up to 125 keV and again opened a new dimension. From x-ray emissions, the fundamental conclusion was drawn later that accelerated electrons were not a peripheral phenomenon, but recipients of a considerable fraction of the primary energy released in flares. At the same time soft x-rays from flares were discovered. They usually peak when the hard x-rays have already disappeared and most of the flare energy resides in the more than 10 million degree soft x-ray emitting plasma. With the discovery of gamma-ray line emission in 1972 by E L Chupp and collaborators, the >1 MeV ion component of flare particle acceleration became accessible. There is now observational evidence for the suggestion that ions get a similar share of the primary energy release as electrons.

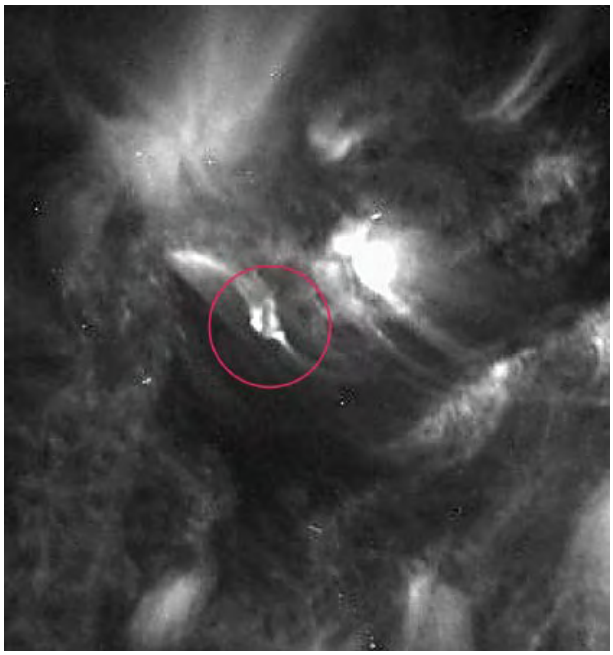

Figure 1. Encircled is the ultraviolet emission of a small flare observed by TRACE. It has resulted from the collision of two expanding magnetic loops. The two loops brightened, in particular the point of contact, where the magnetic field was observed to reconnect. The size of the image is 175 × 175 Mm.

Recent space missions, including SKYLAB, SOLAR MAXIMUM MISSION, YOHKOH and SOHO, as well as new ground-based observatories, both for optical and radio waves, have been essential in the detection of flares outside of active regions. First, CORONAL BRIGHT POINTS in thermal soft x-ray emission were noted, then smaller events in the network of the quiet Sun granulation and finally even in the interior of supergranular cells were discovered. These microflares are about a million times smaller than the one Carrington and Hodgson discovered, and they occur at a rate of thousands per second on the Sun at any time.

A general flare scenario has emerged in which the flare energy is released in the corona and accelerates or heats particles to an energy of 20 keV and more. The particles precipitate into the dense chromosphere, where they collide and deposit their energy. The chromospheric material is heated to the temperatures seen in soft x-rays up to tens of millions of degrees. It expands and adds new high-temperature plasma to the atmosphere above the transition region. The upward motion usually fills up coronal loops, but the motion may continue in an expansion of these loops.

In some cases, the above flare scenario may be only a minor part of a much larger destabilization of the corona, when the magnetic confinement of a considerable part of the corona is removed. It expands and is expelled by magnetic forces in a coronal mass ejection (CME).

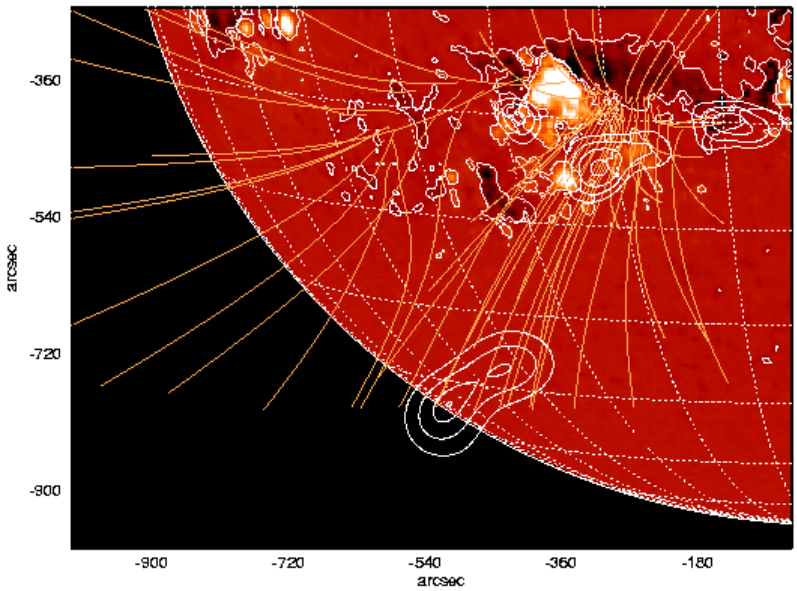

Figure 2. The source region of narrowband spikes, identified with the Phoenix radio spectrometer, has been observed with the Very Large Array at 0.33 GHz. The intensity is presented with contours and is apparently at high altitude, in projection near the solar limb. The photospheric magnetic field is shown in gray scale together with the extrapolated potential field lines. Enhanced thermal radio emission at 1.44 GHz (contours) is also present near the active regions.

The shock front associated with this motion is also a site of particle acceleration, particularly of high-energy solar cosmic rays observed on Earth at ground level.

Types and phases of flares

Flares vary greatly in their spatial shapes and in the relative intensities at different wavelengths. Considering this observed variety, it is not surprising that many attempts have been made to classify flares.

(a) The archetypical flare is impulsive in time and 'compact' in space. It occurs in loops of an active region, which confine most of the energy, i.e. the accelerated particles and the heated plasma. Thus it is also referred to as a 'contained' flare.

(b) A very spectacular class combines large flares occurring at higher altitude. They are often preceded by the disappearance of a prominence and sometimes related to a coronal mass ejection. In view of their longer duration they are called gradual or 'long-duration events', and in Hα they are often seen as 'two-ribbon flares' and 'eruptive'.

(c) High coronal flares occur at even higher altitude. They are responsible for metric type III radio bursts (cf SOLAR SPECTROSCOPY: COHERENT PLASMA EMISSION) and interplanetary electron events, both caused by electron beams propagating into interplanetary space. The energy release may occur at altitudes of half a solar radius or more above the photosphere (figure 2).

(d) In quiet regions of the Sun, flares observed in the emissions of the coronal plasma are very small in energy (some 10^{16} to 10^{20} J) and reach heights of only a few thousand kilometers. They have been termed network flares because of their preferred location above the magnetic network of the chromosphere (figure 3) and may be related to 'explosive events' and 'blinkers' observed previously in the transition region. The largest network flares have been known since the 1970s as coronal bright points (see SOLAR CORONA: X-RAY BRIGHT POINTS).

There is little doubt that the primary cause of the large variety originates in the wide range of possible plasma parameters and unstable magnetic configurations in the energy release region of flares. In active regions of the corona, the magnetic field is generally observed to have a larger scale height than in quiet regions, although the actual energy release may take place on equally small scales and by similar processes. Differences in altitude reflect the change of the global field properties from predominantly closed at low altitudes to partially open at high altitudes.

Flare emissions at different wavelengths do not peak at the same time. The general order of these emissions is shown in figure 4. Flares often start with a brightening in soft x-rays of a few keV due to chromospheric material freshly heated to coronal temperatures. Metric radio emission caused by escaping electron beams indicates that this pre-flare phase is not entirely thermal. The bulk of the flare energy is released in the impulsive phase (or non-thermal phase; see SOLAR FLARES: IMPULSIVE PHASE). Its start is characterized by the onset of hard x-ray (HXR) and centimetric gyrosynchrotron radiation of the energetic

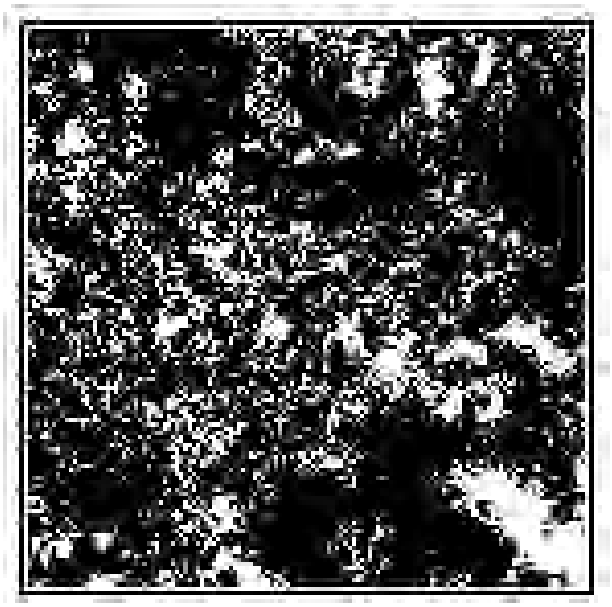

Figure 3. Microflare activity in a field of 280 × 280 solar radii of the quiet corona observed by EIT on SoHO. All pixels that have a $>3\sigma$ enhancement of the coronal emission measure (density) in at least one time step during a 42 min observation are indicated white. The large-scale structures in white follow the magnetic network in the chromosphere below.

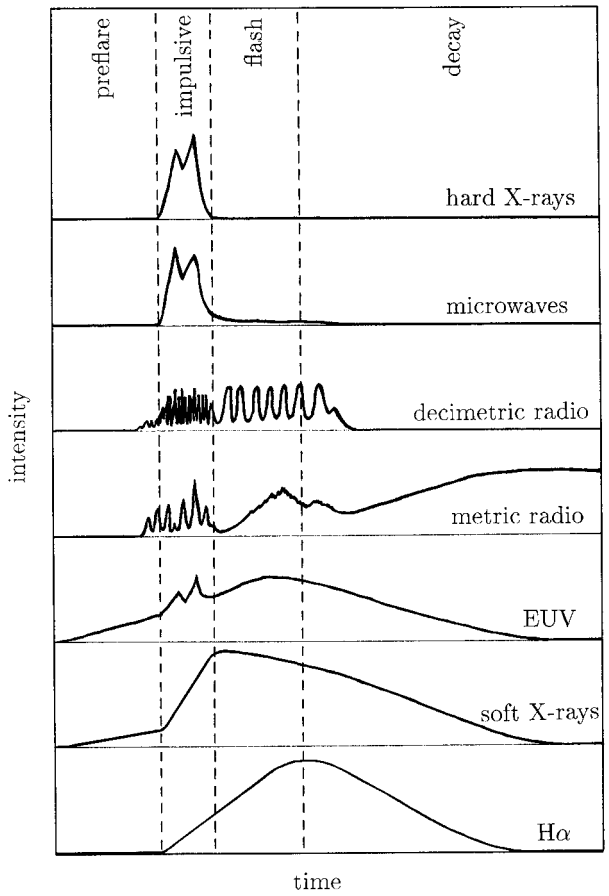

Figure 4. A schematic evolution of flare intensities at different wavelengths. The phases indicated at the top vary greatly in duration. In large events, the preflare phase lasts 10 min, the impulsive phase 1 min, the flash phase 5 min and the decay phase 1 h.

electrons (see SOLAR FLARES: PARTICLE ACCELERATION MECHANISMS and SOLAR FLARES: RADIO BURSTS) as well as gamma-ray line emission caused by energetic ions (see SOLAR FLARES: GAMMA RAYS). Throughout the impulsive phase, the soft x-ray emission increases in size and total flux. Also the lower chromosphere is increasingly affected as evidenced by growing Hα emission. In the flash phase (or thermal or late phase) the non-thermal particles and their emissions have mostly disappeared and the impact of the energy release becomes fully visible. The temperature of the hot plasma decreases. Sometimes, however, gigantic soft x-ray emitting loops cool only slowly and indicate that energy is still released in this phase. Then the flare develops gradually into the decay phase, during which the thermal flare emissions disappear. In the dense flare plasma evaporated into the corona, hydrogen recombines and emits spectacular post-flare loops in Hα. They often show down-moving material. It is the signature of a cooling loop, the density scale height of which is decreasing. Thus the plasma evaporated by the flare is 'raining' back to the chromosphere.

General properties of flares

The typical timing of the observed flare emissions suggests that the major energy release in the impulsive phase transfers the free energy into coronal particles, both electrons and ions. They reach energies far beyond the mean thermal values of the corona. A considerable fraction of this energy has been found in 10–30 keV electrons. A characteristic of this initial particle acceleration is that it produces a power-law in energy distribution of the form $E^{-\delta}$, where δ is between 2 and 5. Electrons reach energies up to 300 MeV, ions up to 10 GeV.

The energetic particles, generally called 'non-thermal', have a much reduced collisional cross section. They spiral along magnetic field lines due to the Lorentz force. A few escape into interplanetary space, but most follow loops and eventually penetrate the denser chromosphere where they quickly lose their energy by collisions.

An impulsive flare of say 10^{24} J is typically spread over an area of several 10^{14} m^2 as seen by its Hα imprint on the chromosphere. Limb flares indicate that such a flare may have a vertical extension of several 10^7 m, and thus a volume of about 10^{22} m^3.

The energization of particles far beyond thermal energies is no surprise since the corona is a plasma with a low ratio of thermal energy density to magnetic energy density. Any relevant release of magnetic energy

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

must therefore produce particles beyond thermal energies. If all the magnetic energy were released in the above example, an average field of 160 G must be annihilated. If this energy is taken up by plasma with an electron density of 10^{16} m^{-3}, each electron and ion receives 30 keV on average. The process that transfers electromagnetic energy into kinetic particle energy is not clear (see SOLAR FLARES: PARTICLE ACCELERATION MECHANISMS). Moreover, the number of electrons required to produce the observed HXR bremsstrahlung is astonishing. The actual value is model dependent and may be of the order of 10^{36} s^{-1} or more.

In an extreme scenario, the flare energy builds up in the corona and all of the flare energy is released there into accelerating non-thermal particles. The electrons are observable in their radio and hard x-ray emissions, the ions in gamma-ray lines. These particles precipitate after a few seconds and dump their energy into small spots of the chromosphere, which heat up to temperatures of several tens of millions of degrees. The larger the flare, the higher is the observed temperature. The hot material, i.e. the flare plasma, explodes due to overpressure and expands along field lines into the corona with a velocity of several hundred km s^{-1}. This phenomenon is observed in transition region lines and is termed 'evaporation'.

The above scenario does not fit all observations. It does not explain why flares usually start with thermal soft x-ray emission, when very few non-thermal particles are observed in the preflare phase. Similarly, the extended heating in the flash phase does not seem to be associated with particle acceleration. Furthermore, the ratio of gyrosynchrotron to soft x-ray emissions decreases to smaller flares, indicating relatively fewer relativistic electrons or smaller lifetimes. For these reasons, occasional or partial direct thermalization without acceleration cannot be completely excluded.

In spite of the large variety, homologous flares occurring at the same site of an active region have also been reported. Homologous flares have similar energy and shape. They occur within hours and suggest a continuous energy build-up that is occasionally released.

Flare sites

Magnetic fields can best be measured in the photosphere, and thus flares can easily be located relative to photospheric magnetic features. As a rule, flares occur above the places in the photosphere with largest $\nabla \times \boldsymbol{B}$, thus where the electric current has a maximum (figure 5). Most productive flare sites are regions in sunspots or groups of sunspots where new and oppositely directed magnetic field emerges from below.

Large, 'gradual' flares often occur above 'neutral' lines in the photosphere, separating regions with opposite magnetic polarity. Neutral lines are bridged by arcades of loops. The Hα picture of flares in such structures shows two bright ribbons formed by the footpoints on each side of the neutral line. Flares usually appear above the part of the neutral line which has experienced most shear by different surface motions on both sides. The first bright Hα point appears near the neutral line. In the course of the impulsive phase, the maximum brightness drifts away to both sides and remains stable during the flash phase.

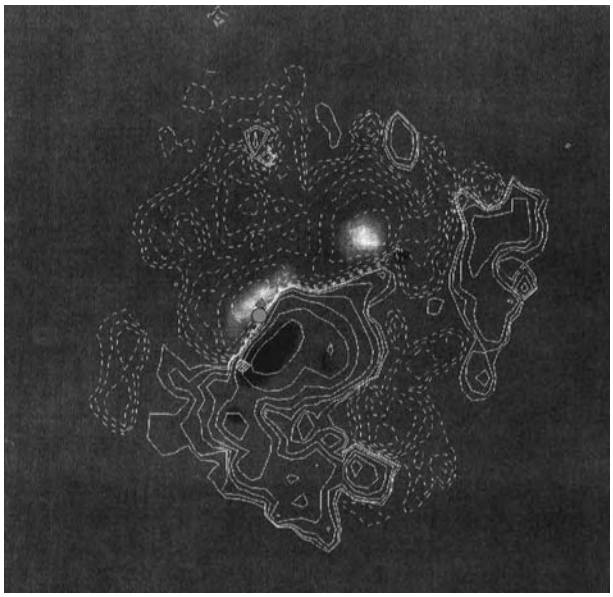

Figure 5. Map of the vertical current density (gray scale), vertical magnetic field (contours), and sites of Hα signatures of non-thermal electron precipitation (gray circle) and high coronal pressure (cross-hatched triangles) (courtesy of R C Canfield).

In quiet regions, the most powerful microflares occur at the boundary of supergranular cells. The cellular structures are formed by large-scale convection below, sweeping frozen-in magnetic field lines to the down-draft region at the surface. There a complex, small-scaled entangled field builds up, the magnetic network. Time scales are a few tens of minutes, over which magnetic elements can be observed to appear and disappear. Enhanced coronal emissions and microflares in soft x-rays and high-temperature iron lines are predominantly associated with bipolar magnetic elements, consisting of a patch of up-going and adjacent down-going magnetic field.

Photospheric observations clearly support the scenario that flare energy originates from electric currents in the corona or, which is equivalent, from free magnetic energy in excess of the potential value defined by the photospheric footpoints. Such currents may arise from the emergence of new magnetic loops penetrating into an old coronal magnetic field configuration. Another possible site is the separatrix between oppositely directed field lines forming a current sheet, e.g. above a cusp-shaped coronal structure. Currents can also build up by shearing or twisting footpoints in the photosphere.

The unifying theme over the past few decades for releasing the energy stored in electric currents has been reconnection. Enormous current densities are necessary to

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

make it happen fast enough. Such high current densities exist only on the scale of a few tens of meters. Thus it is not surprising that there is little direct evidence for the process. In fact, the actual reconnection region cannot have the above volume derived from the energy and particle requirement. Thus it is often assumed that the bulk energy release does not occur in the reconnection region, but in the outflows from it, where shocks and high-frequency turbulence release most of the energy and accelerate particles.

It is not clear whether actual signatures of the outflow from flare acceleration sites have been observed. Potential candidates are hard x-ray sources observed above the soft x-ray loops and occasional narrowband spikes in decimeter radio waves. The narrowband spikes emitted by tens of thousands of sources smaller than about 100 km having electron densities between 10^{15} and 10^{17} m^{-3} are still speculative diagnostics.

Large flares do not consist of a single process continuously releasing energy during the impulsive phase. A fragmentation into 'elementary flares' has been noted first in hard x-rays involving time scales of some ten seconds. The total flux of hard x-ray flare emission often consists of a sequence of such peaks. They are sometimes resolved into shorter structures at radio waves of short centimeter and millimeter wavelength. Also, they loosely correlate with electron beams propagating upward in the corona and visible by their radio emission in meter waves. Both radio emissions strongly suggest an even higher degree of fragmentation. Narrowband radio spikes exceed even this number by another order of magnitude or two. Their duration is only a few tens of microseconds.

The observational evidence indicates impulsive acceleration in a large number of small-scale regions. The flare process thus involves scales from a solar radius for the energy build-up and large-scale instability to about the ion gyroradius of few centimeters for acceleration and energy release. It involves both magnetohydrodynamic and kinetic plasma phenomena.

Effects and consequences of solar flares

The sudden release of energy in the tenuous corona disturbs the fragile equilibrium with the underlaying chromosphere. The transition region that couples the two layers adjusts to the new situation, and these transitory changes are observable in ultraviolet lines and jet motions. In the late phase, the flare energy input into the corona becomes well observable in all thermal coronal emissions.

The role of this impulsive, localized injection of hot plasma for the heating of the corona is not yet fully understood. It is clear, however, that the flares observed in active regions contribute only about 20% of the energy loss by thermal radiations from ultraviolet to x-rays. The flare frequency distribution with energy is too flat to make flares below the sensitivity threshold obvious candidates for the rest. Microflares in quiet regions, on the other hand, seem to be relatively more important contributors and have a steep distribution suggesting a dominant role for the smaller events. The actual value of impulsive energy input is model dependent. At present, microflares are an attractive possibility to satisfy the requirement for coronal heating in quiet regions and coronal holes (see CORONAL HEATING MECHANISMS).

As a rule of thumb, about one particle in a thousand accelerated by a flare escapes into interplanetary space. This number varies over orders of magnitude for different flares, and some particles are accelerated not by the flare process releasing magnetic energy, but by the shock front of the CME. Nevertheless, flares are frequent sources of energetic particles, both electrons and ions, in the solar wind, even though CMEs generally have a more dramatic impact on interplanetary space.

Major flares considerably influence the Earth's upper atmosphere. The prompt effects by flares must be distinguished from impinging CMEs, delayed several days by propagation. The enhanced x-ray emission of flares increases the ionization in the ionospheric D region at heights around 80 km. The increase in electron concentration leads to several phenomena grouped together under the name sudden ionospheric disturbance. The disturbance has a profound effect on the propagation of radio waves. A more dramatic ionization is caused by flare protons in the polar regions of the Earth, where the magnetosphere does not shield against solar cosmic rays.

The average rate of major flares has been up to thousand times higher when the Sun was younger and rotating faster as can be observed for example today on the 70 million year old star EK Dra. The solar activity has markedly decreased after the age of about one billion years. It may increase again for a short time in some 6 billion years, when the Sun will develop into the subgiant branch and the convection layer will temporarily deepen.

Solar Flares: Gamma Rays

Overview

Electromagnetic radiation extends over a very broad range of wavelengths, from gamma rays at the shortest wavelengths to radio waves at the long-wavelength end of the spectrum. In terms of photon energies, gamma rays are at the high end of the spectrum, starting at a few tenths of an MeV. This unit of energy (1 MeV $= 1.6 \times 10^{-13}$ J) is used throughout this article. In solar FLARES, as at many other astrophysical sites, gamma-ray emission results from interactions of fast particles with an underlying ambient medium. These fast particles, protons, α particles, heavier nuclei and electrons, are accelerated from the ambient plasma by the electric fields associated with the complex and varying magnetic fields in the flaring solar atmosphere. Thus, solar flare gamma rays can teach us about the mechanisms that accelerate the particles, in particular those which yield particles with energies in excess of about 1 MeV, the minimum energy needed to produce gamma rays. This is quite important for the understanding of flare mechanisms, because such protons and α particles, along with lower-energy electrons, contain the bulk of the energy released in flares. In addition, the solar flare gamma-ray emission exhibits characteristic spectral lines which provide information on the elemental composition of the ambient solar atmosphere.

Gamma-ray production mechanisms

Solar flare gamma-ray emission exhibits both lines and continuum (figure 1). This theoretical spectrum extends over the entire energy range in which gamma rays from flares were observed. The lines appear at energies from about 0.5 to 8 MeV, whereas the continuum extends up to at least 1000 MeV. Up to about 1 MeV, and again from about 10 to 50 MeV, the continuum is dominated by bremsstrahlung produced by the braking of the accelerated electrons in the Coulomb fields of the ambient nuclei and electrons. The bremsstrahlung produced by ultrarelativistic electrons is strongly collimated along the direction of motion of the electrons. The lines result from the deexcitation of nuclei, from the capture of neutrons and from the annihilation of positrons. The relevant nuclear cross sections are available from accelerator measurements. Deexcitation lines are either narrow or broad. Narrow lines result from the bombardment of ambient nuclei by accelerated protons and α particles, while broad lines result from the inverse reactions in which accelerated C and heavier nuclei collide with ambient H and He. The strongest narrow deexcitation lines are at 6.129 MeV from ^{16}O, 4.438 MeV from ^{12}C, 1.779 MeV from ^{28}Si, 1.634 MeV from ^{20}Ne, 1.369 MeV from ^{24}Mg and 0.847 MeV from ^{56}Fe. The broad lines merge into a quasi-continuum above the bremsstrahlung between about 1 and 8 MeV. The broadening of the deexcitation lines is the consequence of the Doppler shifting of the essentially monochromatic radiation produced in the rest frame of the excited nuclei. In the case of the narrow lines the broadening is due to the recoil velocity of the excited nuclei which is quite small. The widths of the broad lines are much larger because the excited nuclei continue to move rapidly after their excitation.

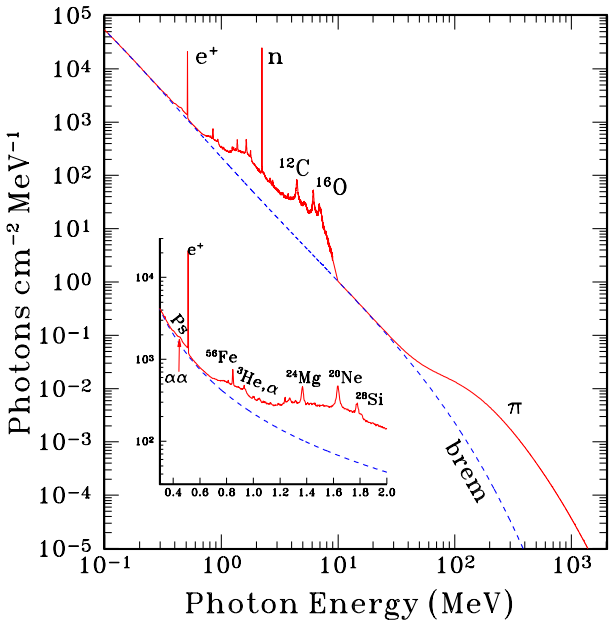

Figure 1. Theoretical solar flare gamma-ray spectrum constructed to fit the observations.

The strong, very narrow line at 2.223 MeV is due to neutron capture. All accelerated ions (protons and heavier nuclei) produce neutrons. The dominant neutron production mode in solar flares is the breakup of He nuclei, both in the accelerated particles and the ambient medium. Along with the deexcitation lines, the neutrons are produced at sites most likely located in the chromospheric portions of magnetic loops. The neutrons propagate both upward, away from the Sun, and downward into the photosphere where they are first thermalized by elastic collisions with protons and subsequently captured mostly by protons to produce deuterium and essentially monoenergetic photons at 2.223 MeV, the binding energy of deuterium. The neutrons moving away from the Sun can reach Earth where they were detected with ground-based and Earth-orbiting instruments. The protons resulting from neutron decay in the interplanetary medium were also detected.

The 2.223 MeV neutron capture line is very narrow because it is broadened by only the relatively low photospheric temperature of about 6000 K. Because the production site of the 2.223 MeV line is situated much deeper than that of the nuclear deexcitation lines, the 2.223 MeV line can be attenuated resulting in limb darkening. This means that, for flares located at or near the solar LIMB, the intensity of the line is much weaker than that of the deexcitation lines, in contrast with disk flares located far from the limb for which the 2.223 MeV line is the strongest.

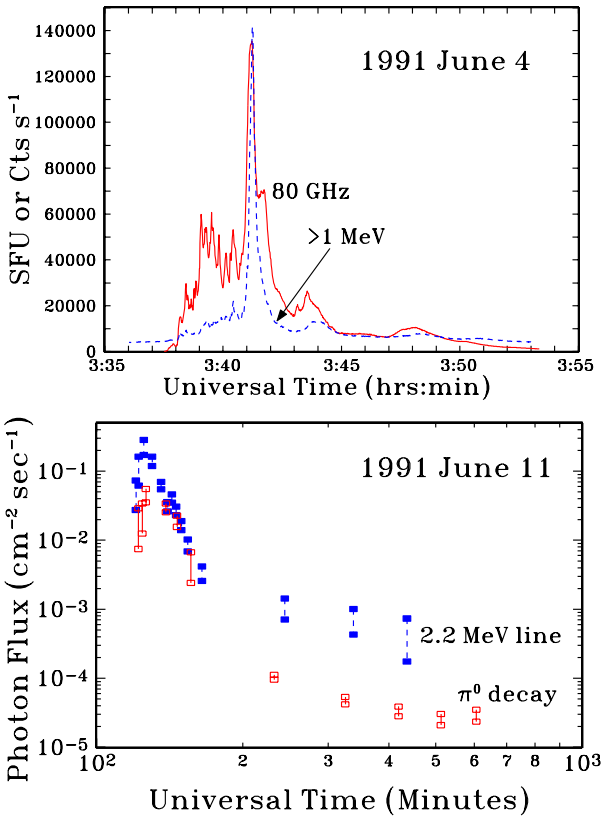

Figure 2. Time dependences. The upper panel exhibits the impulsive nature of the gamma-ray emission, along with the associated high-frequency radio emission. In contrast, the lower shows gamma-ray emission extending over many hours.

A competing mode of neutron capture in the photosphere is that on ^{3}He. This has been used to obtain information on the photospheric ^{3}He abundance.

Another strong narrow line is that at 0.511 MeV from positron annihilation (figure 1). The positrons result mainly from the decay of various short-lived radioactive nuclei, for example ^{11}C, ^{13}N and ^{15}O, which are also produced by interactions of the accelerated ions. The positrons subsequently either annihilate directly into 0.511 MeV gamma rays or form positronium (an atom analogous to hydrogen with the nuclear proton replaced by a positron), which also annihilates into gamma rays. Positronium annihilation leads to both line emission at 0.511 MeV and continuum below this energy. The positronium continuum (denoted by Ps) can be seen in figure 1 at energies just below the e^+ (0.511 MeV) line. The width of this line is very sensitive to the temperature of the medium in which the positrons annihilate. For the calculations of figure 1 it was assumed that the positrons annihilate in the CHROMOSPHERE.

Two strong lines result from the interactions of α particles with He. Fast and ambient ^{4}He nuclei fuse into ^{7}Li and ^{7}Be which are born either in their ground states or in their respective excited states at 0.429 and 0.478 MeV. Because of Doppler broadening, the ensuing deexcitations produce a relatively broad emission feature centered around 0.45 MeV (except under conditions of strong accelerated particle anisotropy when the two lines are narrowed into separate distinguishable features). The combined feature, generally referred to as the $\alpha\alpha$ line, can be seen in figure 1, superposed on the Ps and bremsstrahlung continua. Along with the $\alpha\alpha$ line, there are several other lines which can only be excited by accelerated α particles, as well as lines which are excited exclusively by accelerated ^{3}He nuclei. The latter are of interest because of the very large ^{3}He abundances observed in accelerated particles from impulsive flares (see below). The lines in question are at 1.00, 1.05 and 1.19 MeV and at 0.937, 1.04 and 1.08 MeV from α particle and ^{3}He induced reactions, respectively.

At high energies the continuum in some flares is dominated by pion decay radiation. Neutral and charged pions are produced mostly in high energy (greater than hundreds of MeV) proton–proton, proton–α particle and α–α interactions. Neutral pions decay directly into two photons, while charged pions decay (via muons) into secondary electrons and positrons which produce gamma rays via bremsstrahlung and annihilation in flight. The combined pion decay radiation is shown in figure 1.

The data and their implications

Gamma-ray lines from solar flares were first observed in 1972 with a detector flown on spacecraft. However, it was not until 1980 that routine observations of gamma-ray lines and continuum became possible with the much more sensitive spectrometer on the SOLAR MAXIMUM MISSION (SMM), a spacecraft that carried out successful solar observations for almost a decade. During that period, gamma-ray observations were also carried out with a smaller instrument on the Japanese spacecraft HINOTORI. During the 1990s, solar flare gamma rays have been detected with instruments on the COMPTON GAMMA RAY OBSERVATORY (CGRO). This observatory was launched in 1991, and it is expected that it will continue to operate well into the first decade of the 21st century. Additional solar gamma-ray observations during this period were carried out with instruments on the GRANAT and Gamma-1 spacecraft, which are no longer operational, as well as with a small detector on the YOHKOH spacecraft which continues functioning. Starting in 2000, a new spacecraft, the High Energy Solar Spectroscopic Imager (HESSI), will carry out solar flare x-ray and gamma-ray observations (see also SOLAR FLARE OBSERVATIONS). The main implications of the already available data are the following.

Flare energy release

Hard x-ray observations of solar flares demonstrated that a major fraction of the released flare energy resides in subrelativistic electrons of energies above 0.02 MeV. This, together with the observed impulsiveness of the hard x-rays, strongly suggested that electron acceleration to

these subrelativistic energies is closely associated with the process that releases the flare energy initially stored in magnetic fields. However, prior to the availability of gamma-ray data, the accepted paradigm was that ion acceleration is only a secondary manifestation of the flare energy release process. The gamma-ray emission, however, turned out also to be very impulsive. Moreover, recent studies based on the relative intensities of gamma-ray lines (in particular the ^{20}Ne line at 1.634 MeV) provided new information on the energy distribution of the accelerated ions, requiring very large particle fluxes near 1 MeV. It was shown that the energy contained in such ions is comparable with that contained in the subrelativistic electrons. It thus appears that a large fraction of the released flare energy (approximately 10^{32} erg for large flares) is indeed in accelerated particles, but equipartitioned between ions and electrons. The top panel in figure 2 shows the impulsive time profile of gamma-ray emission produced by ions and electrons of MeV energies compared with very high-frequency radio emission produced by electrons of similar energies gyrating in solar magnetic fields of hundreds of gauss.

Particle acceleration and transport at the Sun

Particles accelerated at or near the Sun are also observed by detectors on spacecraft in interplanetary space. These observations have led to the identification of two classes of acceleration events, impulsive and gradual. Among the various characteristics of the two classes, the composition of the accelerated particles is perhaps the most important. The impulsive events exhibit large enhancements of relativistic electrons relative to MeV protons, of ^{3}He relative to ^{4}He and of heavy ions (particularly Fe) relative to the C and O. In contrast, the gradual events have smaller electron-to-proton ratios (e/p), and their heavy ion abundances and ^{3}He-to-^{4}He ratios are similar to coronal values. The strong association of the gradual events with SOLAR CORONAL MASS EJECTION (CME) suggests that the particles in these events are accelerated by CME driven shocks. On the other hand, the electron, ^{3}He and heavy ion enrichments in impulsive events require selective acceleration which is most likely achieved by gyroresonant interactions with plasma waves.

The gamma-ray observations have independently revealed the characteristics of impulsive acceleration. In particular, high e/p ratios are required by the observed continuum-to-line flux ratios and high ^{3}He abundances are suggested both by the 2.223 MeV line observations, which require enhanced neutron production, and very recent findings in SMM data of ^{3}He induced lines. In addition, there is evidence in the Granat data for highly enhanced heavy ion abundances based on broad lines from Ne, Mg, Si and Fe.

The increased sensitivity of the CGRO detectors and the occurrence of large flares while these instruments were observing the Sun have shown that flares can produce gamma rays for very long periods of time. The data, showing gamma ray emission lasting for up to 8 h after the impulsive phase of the flare, can be seen in the bottom panel of figure 2. It is still not known whether the particles were accelerated in the impulsive phase of the flare and subsequently trapped in magnetic loops at the Sun or accelerated continuously over the duration of the emission.

Additional information on accelerated particle transport at the Sun was obtained from observations of the 2.223 MeV line and electron bremsstrahlung above 10 MeV. The limb darkening of the 2.223 MeV was observed from many solar flares, and it was demonstrated most dramatically by gamma-ray observations of a flare located 10 degrees behind the limb for which the 2.223 MeV line was absent while the deexcitation lines were still seen. Evidently, a considerable fraction of the interactions occurred in the CORONA, at a site which was visible from Earth orbit while the neutron capture site in the SOLAR PHOTOSPHERE was occulted. On the other hand, there is one observation of a behind-the-limb flare from which the 2.223 MeV line was seen. Because of the very strong expected attenuation, the observed 2.223 MeV line must have been produced by charged particles interacting on the visible hemisphere of the Sun. These particles were either accelerated by a coronal shock over a large volume, thereby producing an extended gamma-ray-emitting region, or accelerated locally at the flare site whence they propagated along large loops to the visible hemisphere.

In contrast to the limb darkening of the 2.223 MeV line emission, the bremsstrahlung above 10 MeV was observed to be limb brightened. This means that the flares from which such emission was observed were preferentially located close to the solar limb. This effect is most likely the consequence of particle motion in magnetic loops which converge toward the footpoints with the particles radiating most efficiently when they move parallel to the photosphere near the mirror points.

Ambient medium abundances

SMM and CGRO data on narrow gamma-ray lines have provided information on solar atmospheric elemental abundances (see SOLAR ABUNDANCES). While the C-to-O abundance ratio was found to be consistent with both photospheric and coronal values, the Mg-to-O, Si-to-O and Fe-to-O ratios turned out to be enhanced relative to the photospheric abundances but consistent with those of the corona. The first ionization potentials (FIPs) of Mg, Si and Fe are lower than those of C and O. The enhancement of the abundances of low-FIP elements in the corona relative to the photosphere has been known from both atomic spectroscopy and particle observations of gradual events, but the origin of this fractionation is still only poorly understood. The gamma-ray results, and the fact that the gamma-ray lines are most likely produced in the chromosphere, indicate that the FIP bias sets in already at relatively low heights in the solar atmosphere. Ongoing research on the $\alpha\alpha$ line indicates that in the gamma-ray production region either the α particle or the ambient He abundance is enhanced, exceeding the standard He/H value of 0.1.

Solar Flares: Impulsive Phase

Although impulsive phenomena are commonplace in the universe, solar FLARES are unique in astrophysical research because they provide the largest diversity of observational data, which means diagnostic information available to the observer. Solar flares are truly unique, insofar as they provide the vantage point of seeing the development of impulsive phenomena with high temporal as well as spatial resolution. This also includes the possibility of direct *in situ* measurements of its byproducts, such as accelerated particles in interplanetary space. As we shall demonstrate below, the analysis of all this information has led to the inevitable conclusion that flares are very efficient particle accelerators. A significant fraction of the 10^{28}–10^{33} erg of magnetic free energy that are liberated during an event is released as energetic particles. Since such release occurs in the few seconds to few tens of minutes that it lasts, it is no wonder that the impulsive phase can be considered as the 'core' of the flare phenomenon.

Observations

The impulsive phase of a flare is characterized by a rapid increase in radiation intensity at all wavelengths, spanning from radio frequencies to the gamma rays. Its main characteristic is the ubiquitous presence of rapidly fluctuating bursts of hard x-ray (HXR) radiation, as well as similarly structured and cotemporal emission in the ultraviolet (UV) and extreme ultraviolet (EUV), decimeter and centimeter radiation, and the so-called type III and U radio bursts. In UV and soft x-rays (SXR), the spectra show redshifts and blueshifts in lines formed at 10^5 and 10^7 K temperatures respectively. When looking at its spatial characteristics, the impulsive phase can be adequately described as composed of 'kernels' or 'knots' at all wavelengths, whose area usually represents only a fraction of the, ensuing, 'main phase' of the flare (see SOLAR FLARES: MAIN PHASE). These kernels were first detected, and can easily be seen, in ground-based off-band H-alpha observations as regions of enhanced and highly broadened Balmer line emission (and sometimes continuum enhancements). These characteristics indicate that the emission originates deep in the solar chromosphere or upper photosphere, at layers where the electron density exceeds 10^{13} cm^{-3}. With the advent of space-borne solar observatories, first SKYLAB, then the SOLAR MAXIMUM MISSION (SMM) and HINOTORI and more recently YOHKOH, the concept of impulsive kernels was extended to the EUV, UV and x-ray domains. However, the most definite indication of what, as we shall see, is the basic physical property of the impulsive phase came with the advent of HXR imaging from SMM, Hinotori and Yohkoh. Observations from the SMM spacecraft showed the presence of HXR kernels spatially coincident with the UV and H-alpha knots at the feet of bipolar magnetic loops.

The observations showed, when combined with vector magnetic field observations, that the bulk of the HXR emission was concentrated in loops rooted in highly nonpotential field regions, thus indicating that impulsive phenomena are associated with current-carrying bipoles. The observations also show that, even though the basic structure of a flare consists of a bipolar loop or arcade of loops, the observed impulsive phenomena generally encompass two or more bipolar structures. This suggests that their interaction leads to the impulsive release of magnetic free energy.

Interpretation of the observations

To explain all the phenomena that characterize the impulsive phase, solar physicists have developed over the years a most useful paradigm, the so-called nonthermal thick-target model (TTM). In the TTM, initially developed to explain HXR burst observations, the dissipation of energy, presumably occurring at the top of the loop, first goes into the acceleration of electron beams to energies $\geq$ 20 keV with a power law distribution $AE^{-\delta}$. As these electrons stream down the legs of the loop, they lose energy primarily through electron–electron collisions and produce HXR via a bremsstrahlung process in electron–ion interactions. As long as the ambient loop density is small ($\leq 10^{10}$ cm^{-3}), the beam electrons lose little energy and also produce little HXR emission. However, on reaching the dense layers of the chromosphere ($\geq 10^{12}$ cm^{-3}), both processes increase dramatically and the electrons are stopped, heating the ambient plasma and more efficiently producing HXR photons. It should be noted that only a small fraction, of order 10^{-5}, of the beam energy, is 'used' in bremsstrahlung emission, the bulk is spent in heating ambient electrons with characteristic preflare temperatures $\leq 10^4$ K (see also SOLAR FLARES: PREFLARE PHASE). As with any theoretical model, the power of the TTM resides not only in its ability to explain the data from which it is deduced (in this case HXR burst intensity and spectra), but also in successfully predicting other observational signatures. The TTM predicts the following.

- The HXR emission should be concentrated at the chromospheric feet of coronal loops.
- The upper chromosphere is heated and driven upwards, owing to convective flows caused by the high pressure of the previously cool and dense plasma.
- This hot plasma upflow increases the coronal loop density, causing an increase in its emission measure and, thus, a rise in SXR emission.
- The beam heating also produces a cotemporal increase in transition zone lines' emission (characteristic $T \cong 10^5$ K), which are seen at UV and EUV wavelengths.
- Momentum balance at the transition layer, between the upflowing SXR emitting plasma and the cooler and denser transition zone and chromospheric material, leads to the condensation and downflow of the cooler plasma, causing red-shifted UV lines and asymmetric H-alpha profiles.
- The energy deposition in the deep layers of the chromosphere, due mostly to electrons with energy

Dirac House, Temple Back, Bristol, BS1 6BE, UK

50 $\geq$ keV, causes an increase in visible line emission and the broadening of hydrogen line profiles (such as H-alpha and other Balmer lines), owing to the Stark effect caused by high ($>10^{13}$ cm^{-3}) electron densities.
- Relativistic electrons streaming along the loops produce microwave bursts, because of gyrosynchrotron emission as they spiral along the magnetic field and precipitate to the footpoints.
- Those electrons that escape from the closed bipolar loop, either by getting into open field structures or into neighboring longer-scale bipoles, produce type III and/or reverse U radio bursts respectively. In many cases, H-alpha brightenings are observed at the far end of such loops, in such a close time correspondence to the main flare site that any exciting agent other than energetic electrons is ruled out.

No other model, with perhaps the sole exception of *ad hoc* versions of the so-called thermal model (TM), to which we shall refer in the next section, can account for so many observational constraints. Furthermore, although not explicitly stated in the formulation of the TTM, the acceleration of ions during the impulsive phase can also explain observed gamma-ray phenomena. The interaction of accelerated ($\geq$ 1 MeV per nucleon) ions with ambient nuclei leads to the production of 1–7 MeV nuclear deexcitation gamma-ray lines, the positron annihilation line at 0.511 MeV and the neutron capture line at 2.2 MeV. Reactions of relativistic ions with ambient particles also produce pions and high-energy neutrons. Neutrons with energies between 50 and 500 MeV are produced by protons with up to GeV energies and have been directly observed in space. The pions decay into gamma rays or into ultrarelativistic secondary electrons and positrons, which also contribute to the observed >10 MeV continuum. For a long time it was believed that only a few of the strongest flares produced gamma rays. However, the advent of more sensitive space-borne detectors has shown that the lack of detected gamma-ray emission in many flares may be due to just its weakness rather than its absence. Forthcoming observations, such as those to be obtained with detectors to be flown aboard the HESSI mission, will show whether the great majority of impulsive events are accompanied by high-energy photon and neutron emission. They will also contribute to determining how important, to overall flare energetics, ions are.

The energy and number problem

As we mentioned above, the efficiency of the bremsstrahlung process is very low, so that $\approx 10^5$ erg of electron kinetic energy are necessary to produce just 1 erg of HXR emission that is radiated. We also mentioned that the observed photon spectrum of HXR can be reasonably well fitted by a power law distribution $aE^{-\gamma}$. As shown by J C Brown, R P Lin and H S Hudson and others, in the TTM the energy differential rate at which the electrons are injected into the flaring loop is also a power law $AE^{-\delta}$, where $\delta \approx \gamma + 1$. Then, from the observed intensity or flux of HXRs at 1 AU, one can estimate the total number of electrons accelerated per second at the source. Typical HXR fluxes show that some 10^{35}–10^{37} electrons s^{-1} have to be accelerated to energies $\geq$20 keV in order to reproduce the observed impulsive phase HXR photon spectra. To illustrate the relative magnitude of these numbers, we can mention that a 'typical' quiescent active region loop contains $\approx 10^{36}$ electrons, meaning that the whole electron content of a loop is being accelerated per second. It is also very easy to calculate that the power dissipated in the accelerated electrons' distribution is, for typical impulsive phase parameters, some 10^{28}–10^{30} erg s^{-1} over the 10^2 s duration of the burst. To complicate matters even further, we note that in the largest events the electron number, power and duration of the burst can all be up to two orders of magnitude larger than these 'typical' values. Thanks to the orders of magnitude denser chromospheric reservoir, that can provide a continuous supply of 'fresh' thermal electrons, near-real-time replenishment of the acceleration region may not be a problem. The power issue instead is difficult to avoid. It implies that a substantial fraction of the total energy of the flare resides in accelerated electrons. In view of this, considering that the bulk of the power resides in the low-energy end of the power law distribution, an alternative TM has been widely discussed over the past 20 years. In the TM concept, the lower-energy photons are predominantly emitted by hot (10^8 K) thermal electrons, confined by ion-acoustic turbulent fronts. Since the confined plasma electrons collide among themselves, the ratio of bremsstrahlung to collisional energy loss could, in principle, be orders of magnitude higher than in the TTM. However, the turbulent fronts are 'transparent' to the higher-energy electrons (those with speeds >3 times the thermal speed), so that there is a leakage of high energy electrons that precipitate to the footpoints in a thick target fashion. Considering the aforementioned characteristics of impulsive phase phenomena, such resemblance might be considered a favorable feature, since energetic particle precipitation is needed to explain many of the observations. However, it also means that, in order to explain HXR burst observations, the escaping tail needs to be regenerated quasi-continuously. This reduces the theoretical high efficiency of the TM, and turns it into a hybrid, where acceleration again plays an important role.

New perspectives and the future

It is noteworthy that the first observations ever recorded of a solar flare, by Carrington and Hogdson in 1859, can also be recognized as the first observation of the impulsive phase of a flare. One hundred and forty years later, we are able to understand their white light continuum observations. They are the effect of precipitating high-energy particles into deep layers of the solar chromosphere and upper photosphere. Carrington immediately noticed the close temporal correspondence of the event he had observed to terrestrial disturbances but judiciously refrained from speculating about a cause–effect relationship. Many decades of dedicated research

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

and improvements in observational methods have shown that such a relationship does indeed exist, and this has developed as one of the most dynamic areas of solar–terrestrial research.

We thus find it worthwhile to conclude by pointing out some recent results obtained from ground- and space-borne instrumentation that may still be a subject of debate. First of all, new observational evidence seems to converge towards a view that impulsive phenomena originate at relatively high coronal levels. Radio emission, due to upward and downward directed electron beams, gives an indication that the source of these accelerated electrons is in the corona, at levels where the electron density is of order 10^9–10^{10} cm^{-3} (see SOLAR WIND: ENERGETIC PARTICLES). Observations from the Yohkoh spacecraft have also shown cases of high-altitude coronal HXR emission regions. These sources, detected in flares occurring near the solar limb, are cotemporal with footpoint HXR emission, although considerably weaker, and located above the SXR-emitting loops seen by the spacecraft's SXR telescope. These sources have been interpreted as evidence of magnetic reconnection and energy release above the, already cooling, SXR-emitting loops (see SOLAR FLARE OBSERVATIONS and SOLAR FLARE MODELS). Although their interpretation may still be a matter of debate, the mere existence of the coronal HXR sources signals that suprathermal particles are being generated or injected there, traveling downwards and upwards, as the radio observations suggest. The downward-traveling particles cause the footpoint HXR emission, while those traveling upwards either escape or lead to remote brightenings, when they access large-scale closed field structures.

The most intriguing aspect of impulsive phase physics resides in the mechanism that leads to the release of, say, 10^{30} erg in 10^2 s. This is equivalent (e.g.) to the annihilation of a 100 G field over a $(3 \times 10^8$ cm$)^3$ cube in such a time interval. This is particularly difficult to accomplish under coronal conditions of low resistivity, unless the actual dissipation occurs at spatially unresolvable microscale levels. For many years, radio observations have given an indication of a 'fragmentation' of impulsive phase emission, as evidence of microstructure in the energy release region. This property has been confirmed by observations of prompt and optically thin bremsstrahlung HXR emission, which give direct evidence of the timescales associated with the energization of suprathermal electrons. Observations obtained with BATSE (Burst and Transient Source Experiment) aboard the Compton Gamma Ray Observatory (CGRO) have shown that HXR bursts are composed of both spiky structures due to precipitating electrons and a gradual component with particle trapping characteristics (figure 1). The range of timescales associated with the spiky component ranges from 200 to 1000 ms, which could be associated with dissipation regions with characteristic lengths $\lambda \approx 10^7$ cm.

The resolution of the impulsive phase enigmas will be addressed through a worldwide coordinated program of flare observations to start in the year 2000. Among the observations obtained by ground observatories and spacecraft, a major contribution to impulsive phase studies will be provided by the High Energy Solar Spectroscopic Imager (HESSI) mission. HESSI will obtain HXR images and spectra with an unprecedented combination of spatial, temporal and spectral resolution (2 arcsec to 300 keV, tens of milliseconds, and less that 1 keV FWHM increasing to 5 keV at 20 MeV). With its fine resolution and sensitivity, it will be possible to locate both coronal and chromospheric HXR sources and carry out a numerical inversion of the spectral data. This will help determine the parent electron spectrum as a function of time and energy. Furthermore, HESSI's gamma-ray spectroscopic imaging will provide the first information ever obtained on the spatial distribution of gamma-ray lines and on the spatial distribution of energetic (>1 MeV) protons.

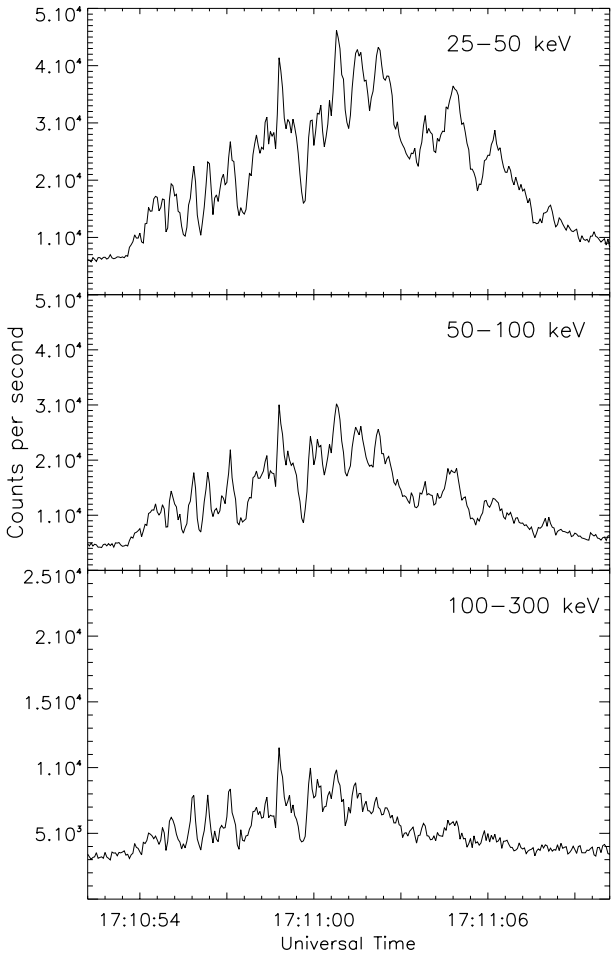

Figure 1. Observations of an HXR burst detected by BATSE in three energy intervals. The temporal resolution is 64 ms, the bin size, and the shortest statistically significant fluctuations observed in this event are in the 200–500 ms range. The burst was associated with an x-ray class C3 flare of 26 June 1991.

Solar Flares: Main Phase

After the impulsive phase of a flare is over (see SOLAR FLARES: IMPULSIVE PHASE), we talk about the main phase or gradual phase. Most FLARES (often called compact or confined flares) are short lived and they simply cool during the main phase, decaying within minutes or tens of minutes. However, there is also another kind of flares (eruptive flares) which continue to release energy during their main phase, and in those flares the decay is much longer: in some events it can continue for many hours. These eruptive flares are much more interesting, because they are often associated with other active phenomena in the solar CORONA which may be sources of disturbances in interplanetary space and in the Earth environment.

Confined flares

The majority of flares (and essentially all subflares) are confined flares—relatively simple structures consisting of one or several brightened loops. It is likely that even those flares which look like a brightened single loop actually consist of more loops which our telescopes are unable to resolve. After the heating process, accomplished during the impulsive phase, these loops begin to cool. This cooling is due partly to heat conduction from the hot flare loop to the cooler CHROMOSPHERE (conductive cooling) and partly to radiation emitted by the loop (radiative cooling) and in some cases also due to mass flow to the loop footpoints. The conductive cooling time increases with the length of the loop, while the radiative cooling time decreases with increasing density. As a flare can consist of a set of loops of various lengths and densities, its cooling is a complex process: short and dense flare loops disappear first, while long and less dense loops survive longer.

In addition to these internal differences in the flare structure, there occur sometimes secondary phenomena that accompany confined flares and eventually may become more impressive, and last longer, than the flare itself. For example, energetic electrons accelerated during the impulsive phase of a flare can stream into a pre-existing larger coronal loop which is rooted close to the flare region, thus forming a less bright, but much larger, structure which, because of its large size and low density, can be seen much longer than the flare which caused its brightening. Another example are flaring arches, in which material of widely different temperatures and densities flows along magnetic field lines from the flare site to another footpoint which sometimes can be located more than 100 000 km afar. In some cases, this material does not reach any secondary footpoint, but just rises and falls back along magnetic field lines, thus creating a flare-associated SURGE. Thus even the 'simple' cooling main phase of a confined flare may be sometimes very complex and not easy to understand.

Eruptive flares

More interesting flares on the Sun belong to the other kind: events in which energy release continues during the main phase. This class comprises a wide energetic range of phenomena which all can be interpreted in the same way: the originally closed magnetic field is disrupted so that its field lines open, and subsequently the open field lines begin to reconnect. The field disruption is often indicated by an activated dark filament which eventually erupts and rises into the corona, but this need not be observed in all events of this kind: sometimes the disrupted configuration is young, or it already disrupted once shortly before, so that there has not been enough time left for plasma to condense and cool to temperatures which make a filament visible in the Hα line.

After the field lines open, mass begins to flow from the dense lower layers to the corona. Therefore, the magnetic pressure begins to prevail over the gas pressure and this imbalance causes reconnection of the open field lines: first fast, low in the atmosphere, where the magnetic field is strongest, and thereafter with progressively slower speed at higher altitudes. As the field lines reconnect, they create new loops at progressively higher altitudes and release energy at the reconnection site, i.e. at the tops of the loops. The loops are formed at very high temperature (close to 20 million K and still higher in the early phase of the loop-system creation) and are first visible in x-rays. Thereafter they gradually cool, so that one can see them in images corresponding to lower temperatures, until they become visible in the Hα line at temperatures below 20 000 K and eventually disappear. As the result of this process we see a growing system of flare loops, in which the lowest loops cool and decay while new ones are formed above them. The growth of this loop system proceeds with speeds of a few, up to a few tens of, kilometers per second at the beginning of the loop system formation and decreases to less than 1 km s^{-1} late in the main phase. Because this process of loop formation and cooling can continue for hours, long after the impulsive phase is over, these newly formed loops are often called post-flare loops (incorrectly, as they actually form the long-lasting main phase of the flare).

The released energy at the reconnection site heats the chromosphere at the loop footpoints which begins to evaporate into the loops, thus enhancing the loop density and making the loops visible. The heating also produces chromospheric emission in the Hα line which is aligned at both sides of the neutral line of the magnetic field, thus creating two bright flare ribbons. As the loops rise in the corona, their footpoints move farther from the neutral line and the two ribbons gradually separate from each other.

The amount of energy released, and thus also the intensity of this chromospheric emission, depends on the strength of the magnetic field in which the process of field opening and reconnection has been accomplished. In very strong fields, i.e. in fully developed ACTIVE REGIONS, we find enormously bright two-ribbon flares, an example of which is shown in figure 1. Essentially all major flares on the Sun belong to this category. In weaker fields the Hα ribbons are less bright, and they may be completely invisible when the process occurs in a very old decaying active region. Such events are then indicated in Hα only by

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

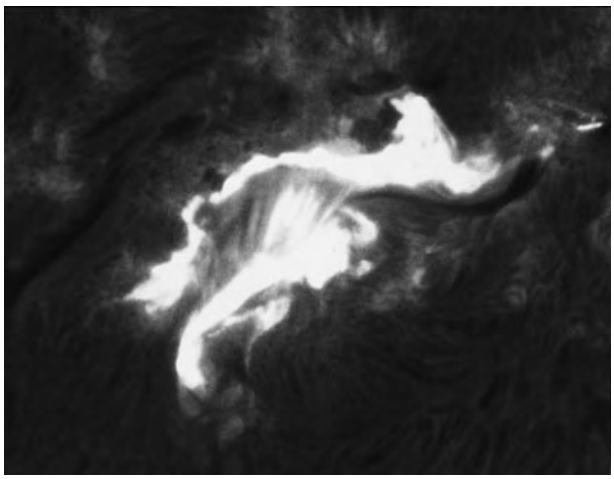

Figure 1. Main phase of a major eruptive (two-ribbon) flare observed in the Hα line at Big Bear Solar Observatory. Two bright flare ribbons extend along the neutral line, marked in the preflare state by a dark filament—its remnant is still visible at the right-hand side of the figure. Inner edges of the ribbons are connected by loops, some in emission and other in absorption.

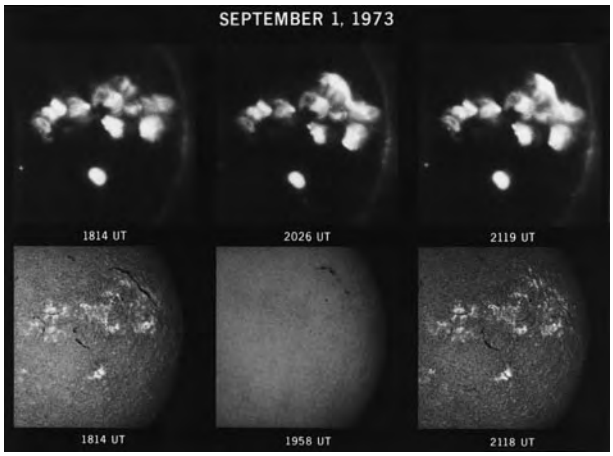

Figure 2. 'Disparition brusque' of a quiescent filament as seen in Hα (below) and in soft x-rays (above, aboard Skylab). The central Hα frame is out of the line center and shows the moving (Doppler-shifted) material of the filament.

the disappearance of an activated dark filament, and have been called disparitions brusques (figure 2). However, all these phenomena, from the disparitions brusques up to the major two-ribbon flares, although accomplished in regions with different magnetic characteristics, represent the same process on the Sun, and, therefore, have been called, all together, eruptive flares.

While in Hα some these events do not look like flares (and, therefore, the term 'eruptive flares' may be somewhat misleading), in x-rays all eruptive flares have one characteristic common: a bright x-ray ribbon-like emission extending along the neutral line at the top of the reconnecting loops (figure 2) and, in consequence of

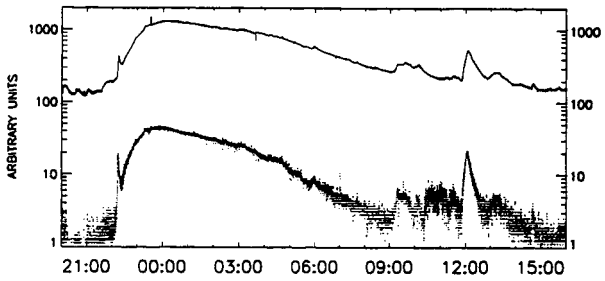

Figure 3. A long-lasting enhancement in soft x-rays (1–8 Å above and 0.5–4 Å below) recorded by the GOES satellite during an eruptive (LDE) flare. The horizontal scale gives time from 21:00 UT on 28 August 1992 through 15:00 UT next day. X-ray enhancements corresponding to confined flares are short lived, like that around 12:00 UT.

it, they all produce long-lasting enhancements of x-ray emission in x-ray records of the Sun (figure 3). For this reason this kind of flares is also called long-decay events, often abbreviated as LDE. Other terms, sometime used for the same phenomena, are dynamic flares or ejective flares.

Complex events

The classification into two classes of flares, confined and eruptive, somewhat simplifies the real situation, because there are also complex flares on the Sun which do not fit exactly any of these two classes. Let us mention the most common cases.

Most (and perhaps all) eruptive flares are related to SOLAR CORONAL MASS EJECTIONS (CMEs). One would expect that one observes the CME first, when the magnetic field disrupts and opens, and only then, through reconnection, the flare itself begins to be formed, but that is not always the case. In some events one begins to observe the flare emission already before any CME is recorded. A likely explanation is that we see first a confined flare, which triggers the field disruption and thus initiates the eruptive flare that follows. In such a case the main phase of the confined flare that triggers the whole process merges with the early phase of the triggered eruptive flare (which, as it seems, needs not always to be impulsive). In some cases a flare is followed in x-rays by an extensive arcade of growing loops which may extend over very large distances on the Sun, far from the original site of the flare. In such cases apparently magnetic field lines opened along a very long portion of the neutral line and subsequently reconnected. However, it is indicated that a substantial part of the field lines stays open for a long period of time and only some of them reconnect. The same may be true, although perhaps to a lesser extent, in all eruptive flares. Then the flaring active regions in which open field lines do not fully reconnect or in which the process of full reconnection takes a long time may become temporary sources of SOLAR WIND.

There are also eruptive flares in which the speed of growth of the loop system does not decrease with time:

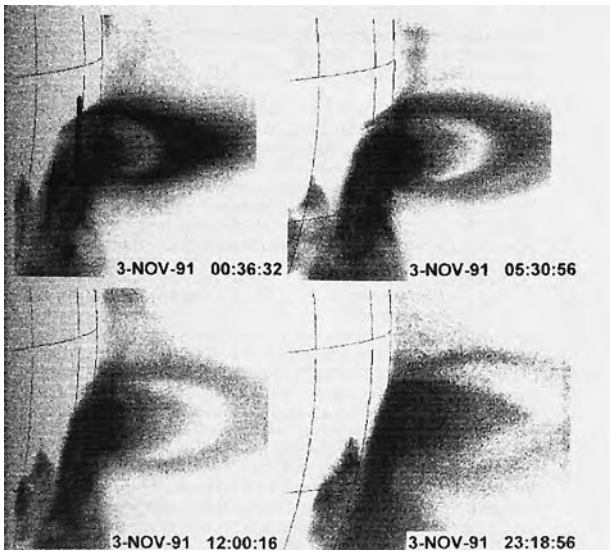

Figure 4. Soft x-ray images of a rising giant arch obtained aboard Yohkoh. The arch followed an eruptive flare of 2 November 1991.

during most of the main phase the loops grow with a constant speed of a few km s^{-1} for many hours. This indicates that the loops are continuously heated, do not cool, and expand.

Coronal main phase

Confined flares may be associated with radio type III or type V bursts (see SOLAR FLARES: RADIO BURSTS) which are related to the flare impulsive phase, but the main phase usually has no response in higher coronal layers. On the other hand, above eruptive flares the solar corona sometimes shows striking changes, and energetic particles (see SOLAR WIND: ENERGETIC PARTICLES), accelerated during the flare, are often trapped in the corona above the flaring active region, where they manifest themselves in several different forms. One can consider these phenomena as the main phase of the eruptive flare in the corona.

On metric radio waves one often observes a type IV burst which is a continuum radio emission, usually consisting of two parts: a moving type IV starting shortly after the impulsive phase and rising in the corona for several tens of minutes and a stationary type IV that appears later below the rising structure. There are also events in which only the stationary type IV is present and, on the other hand, this component may be missing in events observed close to the solar limb. The stationary type IV burst may be very long lived: in some events the continuum gradually becomes bursty and eventually can change into a type I noise storm, which then stays above the flaring active region for tens of hours or even several days.

Soft X-RAY TELESCOPES in space record after some eruptive limb flares coronal phenomena which have been called giant arches. Some of them are stationary, corresponding to lower and denser parts of a stationary type IV burst or a noise storm. While the radio emission is due to gyro-SYNCHROTRON RADIATION or SOLAR WIND PLASMA WAVES, the x-ray emission is produced by bremsstrahlung of the energetic electrons. Other giant arches rise in the corona with constant speeds of 1 or a few km s^{-1} for tens of hours (figure 4). It is likely that these arches are rising loop-like structures, left behind a CME, which begin to expand into the coronal 'vacuum' above them. Although these flare-associated coronal arches can be observed in x-rays only above flares that occur close to the solar limb, they are probably common phenomena characterizing the coronal main phase of eruptive flares.

Solar Flares: Nonthermal Electrons

Solar flares energize particles to different levels, usually subdivided into (1) thermal, (2) nonthermal or energetic and (3) high energetic (figure 1). The lowest energetic level is a thermal particle distribution (where particles have a Maxwellian velocity distribution), produced by Coulomb collisions between the particles of the heated flare plasma. Because the coronal plasma is heated to temperatures of 10–30 million K during a solar flare, thermal electrons have a mean kinetic energy of 0.4–1.3 keV, with tails reaching up to a maximum of about 20–30 keV. The next higher energetic level is referred to as nonthermal particles. Particles acquire nonthermal energies when they become accelerated above the thermal level. Accelerated electrons maintain their nonthermal nature as long as they propagate in a sufficiently low-density (collisionless) plasma so that they do not suffer Coulomb collisions and become thermalized again. Nonthermal electrons with typical energies of 20–100 keV are often observed in hard x-ray and radio wavelengths during flares. In strong flares, particles become accelerated up to 1–10 MeV, referred to as high energetic, and can be detected in gamma ray wavelengths (see SOLAR FLARES: GAMMA RAYS).

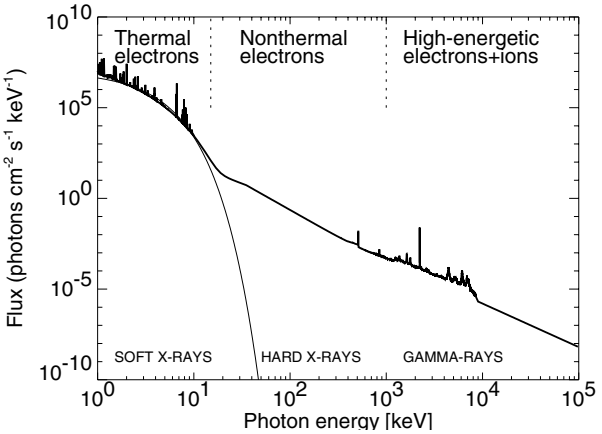

Figure 1. Composite photon spectrum of a large flare, extending from soft x-rays (1–10 keV), through hard x-rays (10 keV–1 MeV), to gamma rays (1 MeV–10 GeV), mostly produced by thermal, nonthermal (energetic), or high-energetic electrons. Gamma-ray line emission and parts of the gamma-ray continuum are produced by interactions of protons, neutrons, ions and pion decay.

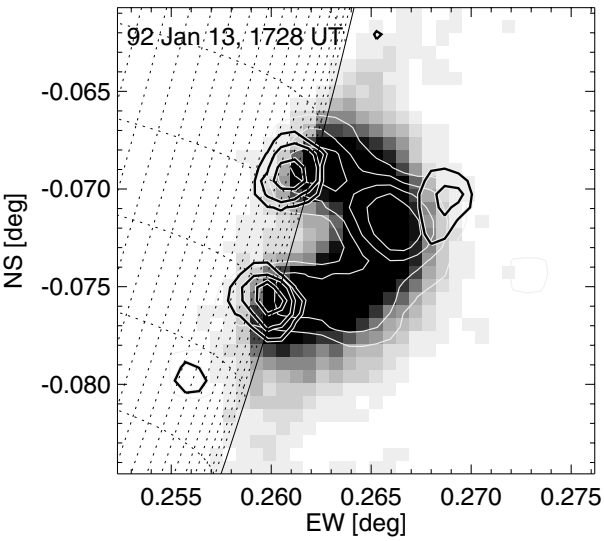

Figure 2. Discovery of the acceleration site of nonthermal electrons by Masuda in the flare of 13 January 1992. The flare loop is bright in soft x-rays (indicated with white contours and grayscale), and shows an above-the-loop-top hard x-ray source (black contours) where electrons are accelerated and two hard x-ray footpoints (black contours), where electrons precipitate to the chromosphere and produce the most intense hard x-ray bremsstrahlung there.

Particle acceleration

Particle accelerators were built in large physics laboratories to study the elementary structure of particles, by analysing the kinematics of high-energetic particles and their decay products in collision experiments. In solar flares, such high-energy experiments take place too, when particles accelerated in the coronal plasma propagate towards the solar surface and collide there with the dense chromospheric plasma. However, how the particles become accelerated in the coronal flare plasma is difficult to probe. There are a number of theoretical models for the accelerations process, such as (1) acceleration by electric fields, (2) stochastic acceleration or (3) shock acceleration (see SOLAR FLARES: PARTICLE ACCELERATION MECHANISMS), but their diagnostics can only be accomplished by remote sensing methods. It was therefore until recently not even clear where the acceleration sites are located in a solar flare. Only the most recent observations by the YOHKOH hard x-ray telescope (HXT) and the COMPTON GAMMA RAY OBSERVATORY (GRO) enabled a breakthrough in the localization of particle acceleration sites.

The most significant discovery was made by Satoshi Masuda, who identified weak hard x-ray sources above flare loops that appear bright in soft x-rays (figure 2). Because the weak above-the-loop-top hard x-ray sources were detected up to 50 keV and their spectrum was identified as nonthermal, they provided for the first time a glimpse of the actual acceleration site. Because Yohkoh revealed also cusp-like plasma structures above the soft x-ray flare loops, the above-the-loop-top hard x-ray sources were brought into context with MAGNETIC RECONNECTION processes. Accurate electron time-of-flight measurements with Compton GRO confirmed that the propagation distance between the acceleration site and the chromospheric footpoints is consistent with the location of the acceleration site found by Masuda. A third piece of evidence for this location of the acceleration site was found from bi-directional electron beams detected at decimetric radio wavelengths, which show electron

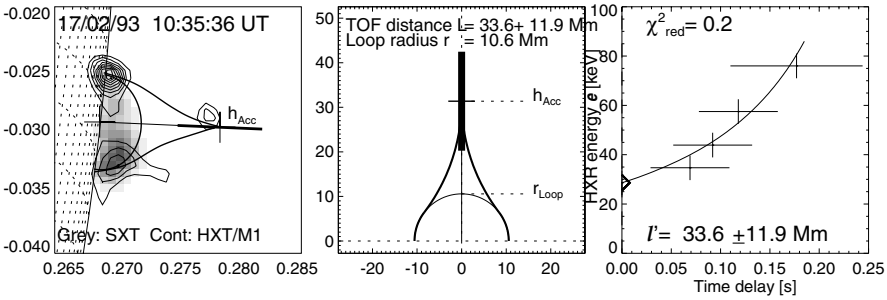

Figure 3. Electron time-of-flight difference measurement between electrons that produce 20–80 keV hard x-ray emission (right panel). From this time difference and a soft x-ray image that shows the loop footpoint separation (left panel), the height of the acceleration site can be reconstructed (middle panel), which is here found at an altitude of 30 000 km.

streams propagating in upward and downward directions, both starting in a common region that has an electron density of $n_e = 10^9$–10^{10} cm s^{-1}, and is thus consistent with the electron densities measured in above-the-loop-top locations. Given this overwhelming evidence, theoreticians can now work with more specific physical parameters to model the acceleration process itself. The above-the-loop-top location is likely to be located in the downward reconnection outflow from an x-point reconnection process, where slow and fast shocks occur and plasma turbulence is created, effects that faciliate both shock and stochastic acceleration. Some new observations with Yohkoh soft x-ray telescope (SXT) and the Nobeyama Radio Heliograph reveal also sometimes large-scale secondary flare loops that have one footpoint in common with the compact soft x-ray flare loop (with hard x-ray emission at the footpoints), suggesting that more complicated loop–loop interactions take place at the acceleration site.

Particle propagation

Once particles are accelerated to nonthermal energies, the ambient plasma becomes collisionless and they can propagate freely along magnetic field lines. The Lorentz force caused by the magnetic field and the particle velocity forces charged particles to spiral along the field lines. The magnetic topology of flares can often be visualized from soft x-ray images, where the heated plasma traces out the magnetic field lines. From such soft x-ray images, e.g. obtained from Yohkoh SXT, it becomes apparent that magnetic field lines connect the acceleration site with flare loop footpoints and thus reveal to us the likely propagation path of accelerated particles. Above the acceleration site, it is likely that the magnetic field lines are open ended and connect with interplanetary space, or close over large-scale arches back to the solar surface at a remote location from the flare site.

The propagation of downward-ejected electrons from the acceleration site has recently been studied by means of time-of-flight differences. Electrons with a kinetic energy of 25 keV have a relativistic velocity of $v/c = 0.3$, while electrons with an energy of 200 keV have a relativistic speed of $v/c = 0.7$. This velocity difference makes the high-energy electrons arrive earlier at the CHROMOSPHERE than the low-energy electrons, if they start simultaneously at the coronal acceleration site. Because the acceleration site has typically a height of 20 000–50 000 km above the solar surface, the resulting time-of-flight differences amount to 100–200 ms. This timing can be measured from energy-dependent time delays of hard x-ray emission, which is produced when the precipitating electrons enter the chromosphere and lose their energy by collisional bremsstrahlung. This time-of-flight method represents therefore an important tool to localize the acceleration site and to probe particle propagation. An example of such a measurement is shown in figure 3.

Particle trapping

Particles injected from the acceleration site onto a magnetic field line can have different velocities and different pitch angles. Because the magnetic field generally increases towards the chromosphere, propagating particles see a converging magnetic field when they approach the flare loop footpoints. Because of the conservation of the

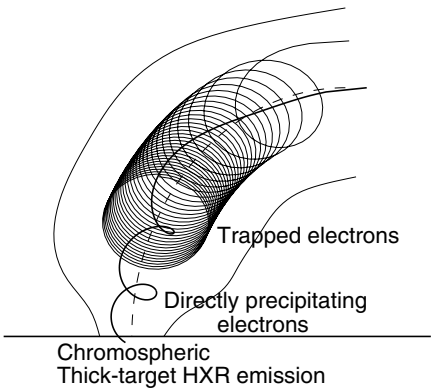

Figure 4. Electrons with small pitch angles precipitate directly, while electrons with large pitch angles become trapped and precipitate after many bounces and eventual scattering into the loss cone.

magnetic moment, the perpendicular velocity or the pitch angle to the magnetic field line increases in response to the increasing magnetic field strength (figure 4). A consequence of this magnetic convergence is that particles bounce back at the bottleneck above the footpoints, called mirror points. This phenomenon of magnetic mirroring is also observed in other converging magnetic fields, e.g. in the Earth's polar cusp magnetic field or in tokomaks. In solar flare loops, mainly electrons with high initial pitch angles become trapped this way and are forced to bounce forth and back between the opposite flare loop footpoints until they suffer a sufficient number of collisions that their pitch angle becomes parallel, which allows the electrons eventually to precipitate. This collisional deflection time τ increases with higher kinetic energy E, according to $\tau \propto E^{3/2}$. This energy dependence of the trapping time was recently confirmed from detailed measurements of hard x-ray delays with Compton GRO.

Hard x-ray and radioemission

Our diagnostics of particle kinematics in solar flares is almost entirely based on their radiative signatures we observe at radio or hard x-ray wavelengths. As long as particles propagate in the collisionless plasma (as is the case in the corona for >30 keV electrons), no hard x-rays are produced. However, when they precipitate towards the dense chromospheric layers, their velocity is slowed down by Coulomb collisions, in which hard x-ray photons are produced by bremsstrahlung. This process illuminates the two footpoints of a flare loop. Flare models that simulate the bombardment of the chromosphere by energetic particles (both electrons and ions) predict a strong local heating of the plasma, resulting in an overpressure that causes the heated plasma to evaporate and to flow upwards into the flare loop. This hot plasma upflow eventually fills the entire flare loop, and thus explains the common appearance of soft x-ray-bright flare loops (marked with SXR in figure 5). This thermal plasma is also responsible for the bulk of hard x-ray emission at energies of 10–30 keV near the loop tops.

Electrons can escape from the acceleration site in upward and downward directions. Because of their anisotropic velocity distribution, propagating electron beams are unstable toward growth of Langmuir waves, which excite plasma oscillations and are converted into electromagnetic waves observable at radio wavelengths. From the frequency–time drift rate of such propagating electron beams, upward (type III bursts) and downward (reverse-slope (RS) bursts) electron beams have been identified in flares. The common start frequency of upward- and downward-injected electron beams is sometimes visible as a separatrix in radio dynamic spectra (figure 5), from which the plasma frequency can be used as a diagnostic of the electron density in the acceleration site. Some upward-moving beams are guided along large-scale arches, which show up in the form of inverted-U bursts in dynamic spectra, or N-shaped bursts, if they are subject to a subsequent mirroring (figure 5). The dominance of closed field lines in active regions explains why a much smaller number of energetic electrons escape into interplanetary space than those that precipitate to the photosphere, as estimated from the hard x-ray flux.

High-energetic (relativistic) electrons, say with energies > 300 keV, emit also gyrosynchrotron emission because of the interaction of their motion with the magnetic field, which is observable in microwaves. Such microwave emission is often seen cospatially with flare loops, with high frequencies closer to the footpoints (because of the higher magnetic field). In summary, most coherent and incoherent radio emission observed in flares is caused in one way or the other by nonthermal electrons and thus

represents an important diagnostic of particle dynamics in flare plasmas (see also SOLAR FLARES: RADIO BURSTS).

Solar Flares: Particle Acceleration Mechanisms

Electrons and ions with energies well into the relativistic regime are a universal feature of solar flares (see SOLAR FLARES: NONTHERMAL ELECTRONS and SOLAR WIND: ENERGETIC PARTICLES). The attainment of these energies poses severe constraints on particle acceleration mechanisms from the viewpoint of timescales, energies, total number of accelerated particles, spectra and the energy of different isotopes and charge states.

Electron energies well in excess of 100 keV, and occasionally up to tens of MeV, are inferred. Electrons are accelerated up to 100 keV in <400 ms and to higher energies in a few seconds. The number of electrons required above 20 keV is large—for x-class flares 10^{37} electrons s^{-1} are inferred, although this number is model dependent and suffers from inadequate hard x-ray data. Information on spectra is sparse. One balloon flight in 1980 with germanium detectors obtained high-resolution (1 keV) spectra in hard x-rays. The data were fitted with a combination of power laws and Maxwellians.

Ions (especially protons) are inferred to have energies in excess of 1 MeV up to $\geq$1 GeV per nucleon. The $\approx$ 10 MeV ions are accelerated on the same timescale as the electrons, with the higher-energy ions being delayed by perhaps 10 s. The total number of accelerated ions is unclear. Traditionally the total energy associated with the accelerated ions was assumed to be much smaller than contained in the electrons, but recent evidence suggests that the energetic ion and electron energy contents may be similar in some flares. The γ-ray spectra are usually power laws. Another important result is the massive enhancement of energetic $^3_2$He in very impulsive flares. This is discussed in the section SOLAR WIND: ENERGETIC PARTICLES.

Efforts to account for these energetic particles are hampered by very limited observations. The poor spectral resolution in hard x-rays and the lack of information on ions with energies below $\approx$ 2 MeV are particularly debilitating. There is also minimal information on the strength and topology of the coronal magnetic field, whose associated energy must be tapped to produce the energetic particles. Nonetheless, in the past decade hard x-ray imaging, in particular from the YOHKOH spacecraft, has begun to shed light on what processes may be responsible for particle acceleration in solar flares.

A variety of possible mechanisms exist that could produce the energetic particles that are inferred to exist in solar flares. The most prominent among them are acceleration by shock waves, magnetohydrodynamic (MHD) turbulence and direct electric fields.

Shock acceleration

Shock acceleration has been invoked widely to account for energetic particles in the solar wind, at the termination shock and at a host of galactic and extragalactic locations. Two types of shock acceleration exist. In one, referred to as shock drift acceleration, particles move along the surface of the shock, gaining energy from the shock electric field. The mechanism is only effective when the angle between the magnetic field and shock normal approaches 90°, and even then the energy gain and particle flux are very limited. Since one would expect shocks to propagate at arbitrary angles, it is unlikely to be the source of the large number of particles accelerated in flares. However, the process may be very relevant in situations on the Sun where small numbers of accelerated electrons are required, such as type II radio bursts (see SOLAR FLARES: RADIO BURSTS).

The second process, called shock diffusive acceleration, occurs when a particle interacts with so-called scattering centers on either side of the shock. If, in the frame of the shock, the scattering centers approach each other, the particle systematically gains energy. This process is similar to that suggested by Fermi in 1949, except that, in the solar flare context, the scattering centers are low-frequency MHD waves generated by energetic particles streaming away from the shock. The mechanism is the same for electrons and ions, with the important restriction that each species must reach a critical velocity prior to acceleration becoming effective. Ions need to have velocities greater than the Alfvén speed ($V_A = B/(\mu_0\rho)^{1/2}$) while electrons must have velocities exceeding at least $(m_i/m_e)^{1/2}V_A$. This is the so-called injection problem. Numerical modelling has shown that it is easily overcome for ions. For electrons it is unsolved at this time.

Diffusive acceleration has been used to account for energetic interplanetary particles but has been less widely applied to impulsive flare acceleration. There are a number of reasons for this. Doubts have persisted that shocks do not form quickly enough to accelerate particles. These doubts are spurious since shocks form on kinetic timescales ($\ll$1 s). Others have questioned whether a flare gives the plasma a big enough impulse to form a shock. Although a flare may appear as a large explosion, the coronal magnetic field is very resistant to compression, and hence to shock formation. There is little doubt that if shocks do form, and particles can reach energies above which diffusive acceleration is effective, they are capable of generating the required particle energies very quickly. Whether the required flux can be produced is unknown at this time.

One particular location where shocks almost certainly do occur is in the vicinity of sites of magnetic reconnection (see SOLAR FLARE MODELS). However, some of these shocks may not be suitable for acceleration of particles. Figure 1 shows a sketch of a flare energy release region (based on suggestive evidence from the Yohkoh satellite) with a pair of shocks trailing away from the reconnection site. The problem is that the shocks are slow mode, corresponding to the steepened slow mode wave. At such slow shocks, the scattering centers do not approach each other, so that no energy gain results. Fast mode shocks have also been proposed in this geometry, as shown in figure 1. It is argued that the high-speed plasma jet that arises during magnetic reconnection interacts with stationary magnetic

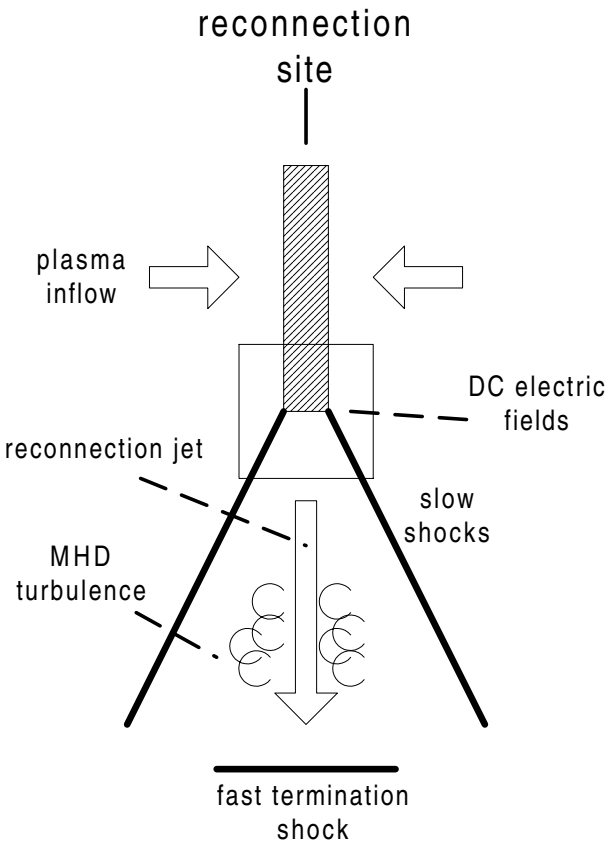

Figure 1. A sketch of a flare energy release region in the solar corona, with possible locations of the particle acceleration mechanisms discussed in this article indicated. The sketch is based on interpretation of hard and soft x-ray data from the Yohkoh satellite. A magnetic reconnection site is assumed to be present, with plasma flowing into it from the left and right sides. The reconnection leads to the generation of a pair of slow mode shock waves, a high-speed plasma jet that may lead to the generation of MHD turbulence and a possible fast mode shock that may terminate the jet. Direct electric fields in the vicinity of the reconnection site itself can also accelerate particles.

fields, resulting in a fast mode termination shock. The role of such a shock in accelerating particles is only beginning to be assessed.

MHD turbulence

MHD turbulent acceleration occurs when particles interact many times with randomly propagating MHD waves. The particles undergo slightly more head-on than overtaking collisions with the waves, so that an energy gain results. The rate of energy gain is slower than for diffusive shock acceleration. MHD turbulence has suffered from the perception that there was an injection problem. In addition, the solution proposed for ion injection at shocks does not work here. The difficulty is that for typical parameters in the solar corona prior to a flare ($T \approx 3 \times 10^6$ K, $n \approx 10^{16}$ m^{-3} and $B \approx 500$ G), a thermal ion or electron cannot resonate with MHD waves. The resolution of this difficulty is similar in concept for ions and electrons, yet different in detail. It should also be noted that all of the models discussed here assume that pitch-angle scattering is efficient enough to maintain an isotropic distribution throughout the time that acceleration is proceeding.

For ion acceleration, the most complete argument proposes that if a fully developed turbulent spectrum of Alfvén waves develops, rather than only long-wavelength waves, thermal ions can interact with waves with frequencies at roughly the ion gyrofrequency. As an ion gains energy, it is continually scattered by longer-wavelength waves, until, when it has a high energy, it resonates with MHD waves. Calculations have been performed indicating that energies of 1 MeV can be produced in 0.1 s, energies of 500 MeV in 2 s for a turbulence level that has magnetic field fluctuations 1% of the ambient field. For the low-energy ions, the majority of the time required to reach these energies is taken up with waves cascading to high frequency.

A similar process of a turbulent cascade, this time of fast mode waves, could operate for electron acceleration, but needs high levels of turbulence. An alternative idea stems from the fact that MHD fast mode waves can accelerate electrons directly by the process of transit time damping. This leads to an increase in the parallel energy of the electron, and so requires ancillary pitch-angle scattering for it to be effective. In fact, for the process to operate, a cascade of energy up the fast mode branch is also required since Coulomb collisions prevent low-energy electrons being energized. Energization of the electrons thus occurs initially through high-frequency waves, with the MHD waves gradually becoming important as the particle energy increases. Initial estimates indicate that the acceleration is prompt (relativistic energies obtained in $\ll 1$ s) and that small volumes (10^{19} m^3) can produce roughly 10^{34} electrons with energies above 20 keV. A flare is then the sum of many of these small energy release regions.

While MHD turbulence is clearly an attractive acceleration mechanism, its possible origin in solar flares is not fully clear. By examining the spectral profiles of coronal emission lines, it is clear that there are significant random motions during flares that may correspond to MHD turbulence. However, these observations have no spatial resolution so that it is unclear where the turbulence is located. One speculation is that the turbulence is the result of an instability in the high-speed plasma flows associated with magnetic reconnection in, or at the top of, flare loops as shown in figure 1. The latter hypothesis is especially attractive given the Yohkoh observations of hard x-ray emission from high in the corona.

Direct electric fields

Direct electric field acceleration may occur in flares in two different forms depending on the strength of the electric field. The key parameter is the field strength that leads to an electron moving at the electron thermal speed gaining energy indefinitely. This is defined as the Dreicer electric field ($E_D = (e/4\pi\epsilon_0)(\omega_{pe}/V_{Te})^2 \ln\Lambda$ V m^{-1}). For typical

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

preflare parameters ($T_e = 3 \times 10^6$ K, $n = 10^{16}$ m^{-3}, $\ln \Lambda = 20$), $E_D \approx 10^{-2}$ V m^{-1}. If $E < E_D$, then only the tails of the electron distribution functions are accelerated. If $E > E_D$ then most electrons will gain energy. In the magnetic reconnection model shown in figure 1, $E \gg E_D$, with 100 V m^{-1} being a plausible value, but other scenarios have been proposed with $E < E_D$.

When $E < E_D$ the energy gain that particles attain is limited by the flare geometry, i.e. the length of the potential drop. For a flare loop length of 5×10^7 m, one is limited to 500 keV, lower than the maximum electron energies inferred from γ-ray emission. The ion energies are much lower than required. However, the process may be capable of reproducing hard x-ray spectra below 100 keV. The acceleration time is short, and significant fluxes of electrons can be generated. For $E > E_D$, high energies are readily attainable. Particles of energy 1 MeV can be produced in 10^4 m, a much smaller distance than the resolution of current observations. Ions with energies >1 GeV may pose more significant problems to the mechanism.

The limitation on both mechanisms is the need to ensure overall quasi-neutrality of charge and current in the acceleration regions. Since the inferred number of energetic particles requires that a significant fraction of the coronal population be accelerated, an efficient means of repopulating the acceleration site is required. Also, the accelerated particles correspond to a significant electric current, that in turn will generate large magnetic fields if the current is unneutralized. The resolution of these problems is straightforward for acceleration by shocks and MHD turbulence and is accomplished by a return current of low-energy thermal particles travelling from chromosphere to corona. The return current is oppositely directed to the current due to the accelerated particles, so that only weak magnetic fields are generated. The low-energy electrons also permit overall neutrality to be maintained in the acceleration region. Here the return current flows unimpeded, since no direct electric field acts to oppose it. However, when a direct electric field is present, it will accelerate particles in one direction, and so a return current cannot flow cospatially in the same direction. The problem is especially acute when $E < E_D$ since long potential drops are required. The resolution is to propose that the acceleration site is composed of millions of oppositely directed electric fields such that in an average sense there is approximately no net current or charge deficit. The problem is less severe when $E \gg E_D$ provided that the particles can escape from the electric field before a large current builds up, but precise calculations have yet to be performed.

The future

In recent years, interpretation of satellite data and theoretical modelling have led to major advances in our understanding of particle acceleration mechanisms in flares. While the models still do not address particle acceleration in the global flare context in an adequate manner, the understanding of the plasma physics of the acceleration mechanisms has improved greatly for all of the competing mechanisms. While it is to be expected that progress will be made on the theoretical understanding of mechanisms in the next few years, the major advance in this field is likely to come from the high spectral and spatial resolution at hard x-ray and γ-ray wavelengths made possible by the instruments to be launched on the NASA High Energy Solar Spectroscopic Imager (HESSI) spacecraft in mid-2000.

Solar Flares: Preflare Phase

Solar flares are believed to be the result of a sudden conversion of a large amount of free magnetic energy, previously stored in the solar CORONA. The release takes place in a matter of minutes to half an hour, and the amount of energy involved can be up to 10^{26} J (10^{33} erg).

It is generally accepted that in the preflare phase this magnetic energy is slowly built up in the corona, in a matter of hours to days. The sudden release may then be triggered by the onset of a MAGNETOHYDRODYNAMIC (MHD) instability, by 'loss of equilibrium', or by other triggers. Solar physicists have for a long time studied the preflare phase to try to understand the mechanism for the supposed build-up of of magnetic energy, and for a clue to the trigger mechanism. The purpose of these studies is to try to develop the tools to identify regions that are likely to flare and some day to be able to predict the location, time, type and intensity of flares. Moreover, a good physical understanding of the preflare build-up and the trigger mechanism is at the heart of understanding the physics of solar flares as a whole.

Multiwavelength observations of the preflare regions are clearly needed for studying the preflare phase. These observations suffer from the fundamental difficulty that the defining event—the flare—takes place at the end of the observing sequence. A preflare observing campaign therefore often consists of the identification of a 'promising' solar region and then leaving the participating instruments and observatories in a 'sit and stare' mode for as long as it takes. The day–night cycle for ground-based observatories and for earth-orbiting spacecraft very often frustrates this endeavor. Experiments on the recent SOHO mission (which orbits the Sun and therefore has an uninterrupted view) have been quite successful in following regions with a flare promise for more than a day. Future observations from a fleet of spacecraft, in solar orbit and positioned at different angles from the Sun (the 'Stereo' mission) will further eliminate the two week limit of visibility of any promising region, due to the rotation of the Sun itself, and further allow a three-dimensional view of the structures involved.

In the following section the observational results to date on flare precursors will be reviewed. After that the observational signatures for the magnetic energy build-up and changes in the magnetic field structure in preflare regions will be summarized. The article concludes with a description of the basic requirements for theoretical models of preflare energy build-up and the triggering of a flare.

Flare precursors

The categorization of precursors by Gaizauskas (1989) will be adhered to here. His definition of a precursor is a transient event preceding the impulsive phase, possibly even before the onset, and not necessarily at the site of the flare itself (figure 1). Sometimes the frequency of occurrence of minor flares reaches a maximum just before a major flare. In that case the minor flares may qualify as precursors.

Homologous flares

Homologous flares are earlier flares in the same location with similar emission patterns. They occur most often in periods of frequent flare activity. The rate of repetition in a homologous series ranges from a few per hour to several days. There is no consistent relationship between repetition rate and brightness in x-ray, optical or microwave emissions. It is expected that the same flare-producing stress acts on the regions for hours and days, and indeed it has been found that homology is clearly correlated with the development of magnetic shear in an active region, but strict homology is never realized because of the ongoing evolution of small-scale magnetic fields.

Sympathetic flares

Sympathetic flares are earlier flares in different locations, but erupting in near synchronism. Soft x-ray images of the solar corona clearly demonstrate the existence of multiple links between adjacent, and even remote, active regions. Along these links a single excitation could, in principle, be transmitted to other sites and trigger flares. Statistical tests of large samples of flares have been inconclusive, but the analysis of individual cases has shown unequivocally that one flare can trigger another.

Soft x-ray precursors

Soft x-ray precursors are transient enhancements in soft x-rays, lasting for several minutes, that occur in loops or unresolved kernels at, or close to, flare sites. Their shape and location may coincide with those of the subsequent impulsive phase, but that coincidence is usually only partial. Weak soft x-ray bursts are often observed at the time of the projected onset of a SOLAR CORONAL MASS EJECTION (CME) associated with a flare. This may be tens of minutes prior to the impulsive phase of the flare, and the location is usually at one foot of a large pre-existing coronal arch. The rest of the arch brightens weakly within minutes, and the outward motion of the x-ray emitting plasma indicates that a CME has been launched. One interpretation of this sequence of events is that a small magnetic structure interacts with the large coronal arch at one of its footpoints (seen as the precursor), destabilizing the whole structure. This global instability then causes the launch of the CME and the onset of a flare at one of its footpoints.

Radio precursors

Radio precursors, most often observed in microwaves, consist of changes in intensity and/or polarization of radiowaves emitted from an active region, tens of minutes before the onset of a flare. Statistical studies indicate that radio precursors do not occur for the majority of flares, although the correlation between radio bursts and flares is significant. Also, preimpulsive bursts may have very narrow spectral bands, so that most are missed by single-frequency radio telescopes. Individual

radio precursors observed at high resolution show morphological transitions of the emitting structures for tens of minutes through the preflare and impulsive phase, while there are also dramatic changes in polarization in centimeter wavelengths from minutes up to an hour before the flare, continuing through the impulsive phase. These results indicate a preflare reorganization of the magnetic field, but the exact nature of this reorganization (flux emergence, reconnection, eruption, etc) cannot be determined from the radio data alone.

Ultraviolet precursors

Ultraviolet (UV) precursors are mostly small-scale transient brightenings above active regions, and they exhibit a broad range of amplitudes. Some of the UV kernels coincide with the later flare, but in other cases the flare may be concentrated in nearby new kernels. Repeated transient UV brightenings have been observed in association with the upwelling, twisting and disruption of an active region prominence just prior to a two-ribbon flare. However, there is not enough statistical evidence to reliably identify a UV flare precursor against the varying UV background.

Surging arches

A surging arch is a transient absorbing feature visible at wavelengths displaced from the central core of Hα. Simultaneous red- and blueshifted components are also visible from the first appearance of the arch, but they are not cospatial. The arch is initially straight in shape (seen from above), expands rapidly and unravels in multiple strands by the time the associated flare erupts in the same active region. In a statistical study of 58 flares it was found that just over half were preceded by a surging arch.

The common inference from the variety of flare precursors described above is that up to tens of minutes prior to the impulsive phase of the flare coronal plasma is heated and set in motion by a rearrangement of the coronal magnetic field. This rearrangement accelerates from gradual to explosive at the onset of the impulsive phase of the flare.

Prominence eruptions and coronal mass ejections

SOLAR PROMINENCE ERUPTIONS very often, but not always, precede two-ribbon flares, the most energetic and long-lived flare type. CMEs are also often associated with a two-ribbon flare. In fact, the extrapolated launch of the CME precedes the prominence eruption and flare in most events, but this launch is difficult to observe. The time delay between the onset of the prominence eruption and the impulsive phase is of the order of minutes, but activity such as enhanced mass motions inside the prominence, a slow rise of the prominence and untwisting can precede the main flare by hours. Enhanced mass motions in active region prominences are the earliest sign of an impending flare and form one of the best flare predictors.

However, not all flares, not even all large ones, have associated prominence eruptions, and not all prominence eruptions lead to flares. While some observers claim there are indications for the eruption of a magnetic flux tube in all flares, other soft x-ray observers claim there is ample evidence for a class of flares that involves the interaction of two or more magnetic loops without an eruption. What seems clear is that at least for two-ribbon flares the prominence eruption is direct evidence for a preflare rearrangement of coronal magnetic field, setting the stage for the sudden energy release that causes the flare emissions.

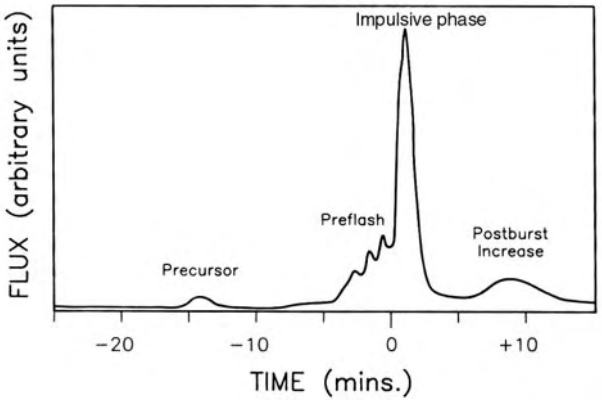

Figure 1. Idealized flux profile of a flare detected in an energy band that senses a distinct impulsive phase (after Gaizauskas 1989).

Magnetic field structure and evolution

The precursors described above are mostly indirect indicators of changes in the coronal magnetic field prior to a flare. A direct signature of these changes comes from observation of the magnetic field in the corona and photosphere. Because of the high coronal temperature only infrared lines are really suitable to measure the magnetic field in the corona, and those have not been explored sufficiently yet. Observations in soft x-rays and the UV show CORONAL LOOPS, which outline the magnetic field morphology. Hα observations show cool matter in filaments or arches that is either streaming along the field or resting at the bottom of slings in the magnetic field, thus yielding additional clues to the magnetic field structure.

Vector magnetic field measurements

More quantitative information can be extracted from the photospheric magnetic field. Here both the line-of-sight and the transverse magnetic field component can be measured in a usually thin layer where the specific line is formed (see the article on SOLAR MAGNETIC FIELD: INFERENCE BY POLARIMETRY). The three components of the magnetic field then can be deduced after removing the sign ambiguity in the transverse magnetic field component, which can be done in several ways, all based upon plausibility arguments. These vector magnetic field measurements have been carried out since the early 1980s at several ground-based solar observatories, and their resolution has increased with newer equipment becoming available.

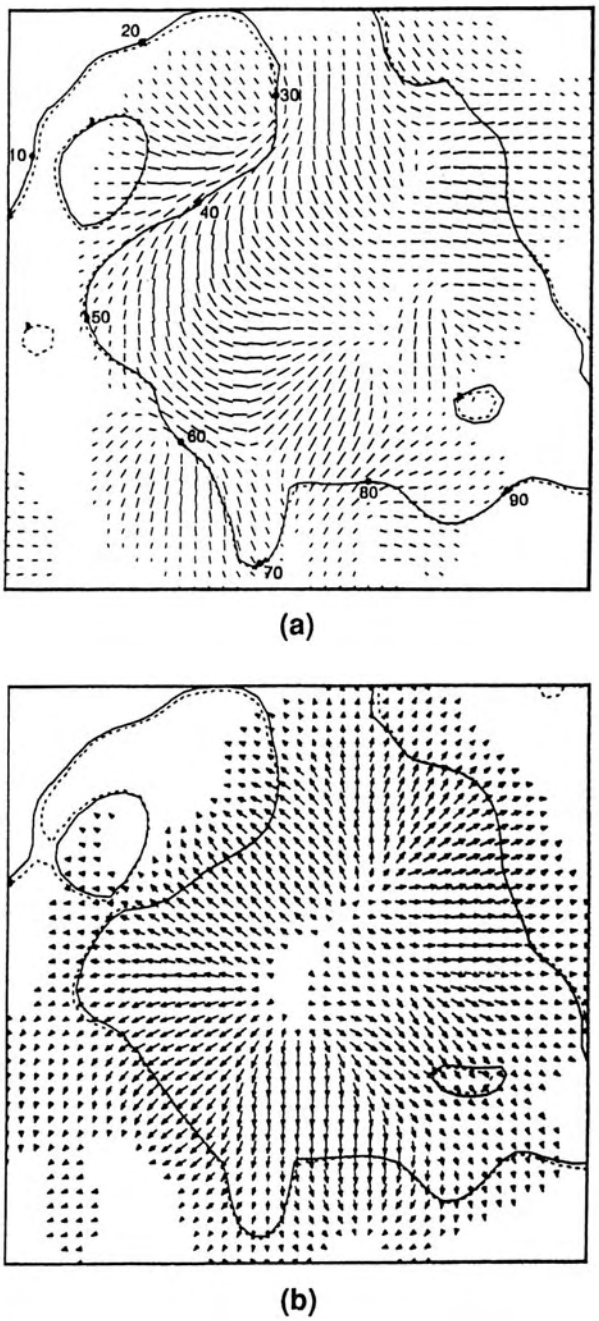

Figure 2. The transverse magnetic field of AR 4711 (*a*) measured by the Marshall vector magnetograph on 3 February 1986, at 16:42 UT, compared with the potential field direction (*b*) calculated from a line-of-sight magnetogram. The region of the largest shear along the polarity inversion line, between points 30 and 50, will be the location of a flare about 4 h later. The field of view is 110 by 110 arcsec, and north is up (from Hagyard 1990).

The magnetic field in the corona can be calculated from the vector magnetic field measured at the lower coronal boundary if one assumes a force-free state for the coronal magnetic field. This assumption is very sensible for two reasons: (1) the observed velocities in the corona are very low compared with the Alfvén velocity, and hence the field is quasi-static, and (2) the gas pressure in the corona is much lower than the inferred magnetic pressure. Therefore the Lorentz force cannot be balanced by either gas or flow pressure gradients over large areas, and the magnetic field must be close to force free. Practical methods have been devised to calculate a force-free field with known vector magnetic boundary conditions, although neither the existence nor the uniqueness of the solutions is guaranteed.

Coronal magnetic fields calculated from the measurements of vector magnetographs show satisfactory agreement with the above-mentioned observed coronal field morphology. Observations of flare sites prior to the impulsive phase have confirmed the scenario of a gradual build-up of free magnetic energy, and yielded several additional clues to the cause of the sudden release of that energy. Hagyard (1990) emphasizes the importance of angular shear, i.e. the angle between the observed transverse field and the potential field that can be derived from the line-of-sight component of the magnetic field alone (figure 2). From the analysis of a sample of only four flares she found that these flares occurred in an area where the local photospheric field departed the most from a potential field. For all flares the magnetic field was strong and the maximum angular shear was at least 85°, while over an extended interval of 8000-10 000 km the shear angle was larger than 80°. It has been claimed that these are sufficient conditions for a flare, but the exact timing for the ensuing flares cannot be determined, so exact flare prediction remains an elusive goal. Clearly, however, vector magnetic field measurements represent the most direct and physical approach towards SOLAR FLARE FORECASTING.

Magnetic field complexity and evolution

Extreme magnetic complexity has long been recognized as very advantageous for producing great flares. Complexity in the magnetic field can be present from the moment the magnetic flux emerges, while in other cases it is fabricated when several sunspot pairs collide and interact.

Numerous flares have been observed to erupt in the vicinity of emerging flux, while the opposite process, flux cancellation, has also been shown to lead to the formation of prominences and to trigger their eruption and the subsequent flare. Large flares often erupt in areas where old and new magnetic flux interacts. An empirical rule here is that prior to a flare the magnetic features of one polarity are increasing, while nearby features of opposite polarity are decreasing.

Chromospheric fibrils (see CHROMOSPHERE: FIBRILS) adjacent to the magnetic polarity inversion line usually stretch nearly parallel to it, indicating a strong magnetic shear in flare-prone regions, in agreement with vector magnetograph observations. Rapid SUNSPOT motions and high inferred velocity shear (i.e. a rapid variation of the

P C Martens

magnitude of the horizontal velocity in the horizontal direction perpendicular to the velocity) are known to correlate with increased flare activity.

There is no evidence that complexity, flux emergence or cancellation are sufficient conditions for flares, since all can occur without ensuing flares. What the above observational results indicate is the importance of considering the evolution of the magnetic field. Free (i.e. non-potential) magnetic energy can be transferred from the photosphere into the corona during the evolution of the magnetic field, both through shearing motions of existing magnetic fields and through emergence of new current-carrying field. At the same time the cancellation of photospheric flux elements can reconnect coronal magnetic loops at their footpoints, changing the connectivity of the coronal field and destabilizing it.

Modeling the preflare phase

The task for the theorist in modeling the preflare phase that emerges from the description of the observational results above is clear. In the preflare phase the magnetic field evolves quasi-statically through a series of force-free states in response to slow changes in the photospheric boundary field. Because of the low electrical resistivity in the corona ideal MHD may be assumed, so no large scale reconnection takes place and the field line connectivity is maintained. The footpoints of field lines are moved around by the photospheric motions, and the coronal magnetic field adjusts by evolving through adjacent force-free states with identical connectivity. New flux elements may be introduced to account for the process of flux emergence. Flux cancellation may represent a deviation from ideal MHD at the photospheric boundary and can be modeled as a boundary change in the fieldline connectivity and magnetic topology.

The simplest model for flare energy build-up therefore consists of calculating a series of topologically connected force-free equilibria that corresponds to a physically meaningful series of photospheric boundary conditions (e.g. continuous motions, finite velocities). At some point in the series the magnetic field may become linearly unstable, and it may be assumed that at that point a dynamical evolution on a much more rapid time scale will set in; the onset of the flare. The same response may occur at a point where no adjacent force-free equilibrium is available, a so-called catastrophe point. A detailed discussion of several of such currently prevailing models is presented in the article on SOLAR FLARE MODELS.

Solar Flares: Radio Bursts

Energy release in solar flares heats plasma and accelerates electrons and ions to high energies. Radio bursts of various types are produced by energetic electrons interacting with the ambient plasma or with the magnetic field. They may be divided into two broad classes according to frequency range and the dominant emission mechanisms. (1) Coherent plasma radiation plays a dominant role for burst phenomena that occur at meter and decimeter wavelengths (frequencies $\nu \lesssim 3$ GHz). Plasma radiation results from the nonlinear conversion of electron energy to plasma waves and from thence to electromagnetic waves at a frequency near the local plasma frequency or its harmonic (see SOLAR SPECTROSCOPY: CONTINUUM RADIO EMISSION AND DIAGNOSTICS). Plasma radiation is rarely a factor at higher frequencies, where it experiences strong free–free absorption. (2) Incoherent gyrosynchrotron radiation dominates burst activity at centimeter and millimeter wavelengths ($\nu \gtrsim 3$ GHz). Gyrosynchrotron radiation is due to electrons with energies of tens of keV to a few MeV gyrating in a magnetic field at the local electron gyrofrequency. Thermal or nonthermal distributions of such electrons emit a broadband continuum of radiation. Gyrosynchrotron radiation is relatively unimportant at frequencies $\lesssim$1 GHz because the radiation is strongly self-absorbed and/or masked by free–free absorption in overlying plasma.

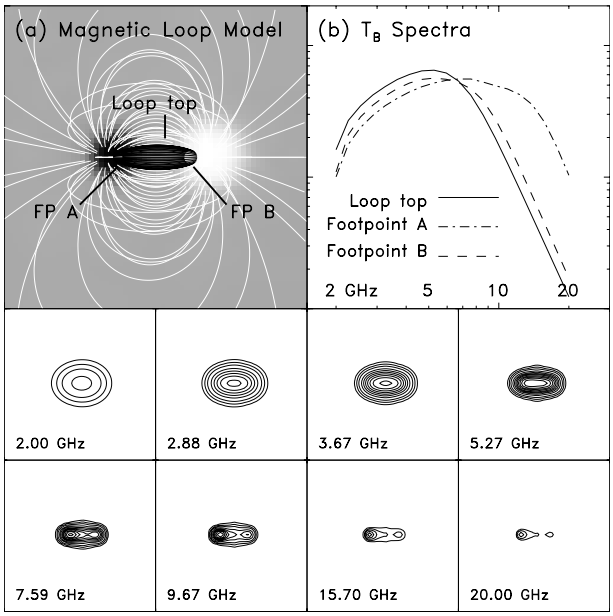

Figure 1. A schematic model of gyrosynchrotron emission from a single asymmetric magnetic loop. Top left: the magnetic loop model. Top right: brightness temperature spectra at the two footpoints and the loop top. Bottom panels: the brightness distribution in total intensity at the frequencies indicated.

Bursts at meter and decimeter wavelengths

At meter wavelengths, radio bursts of types II, III and IV accompany flares (see SOLAR FLARES: RADIO BURSTS). Type II radio bursts, the result of plasma radiation associated with a magnetohydrodynamic shock propagating through the corona, are well correlated with flares. More than 90% of type II bursts have an associated flare. Not all flares produce type II bursts, however. They are rarely seen in association with flares with an Hα importance less than 2 but they accompany 30% of flares with an Hα importance of 2 and 3. However, because small flares are more common than large flares, type II radio bursts are nevertheless more commonly associated with small flares. Type IV bursts are a broadband continuum usually seen in association with type II bursts. Both type II and type IV bursts have a close association with coronal mass ejections (CMEs). Roughly 70% of all type II bursts are associated with a CME. Whether coronal type II and/or type IV radio bursts are produced by CMEs or by the blast wave from an associated flare remains controversial (see SOLAR FLARES: RELATION TO CORONAL MASS EJECTIONS).

Type III bursts occur whenever active regions are present on the Sun. Hence most occur during times when flares are absent. Type III bursts are due to beams of suprathermal electrons propagating upward in the corona. Dynamic spectra of type III bursts are characterized by frequency drifts from high to low frequencies as the beam excites plasma waves at lower densities with increasing height in the corona. More interesting as a flare phenomenon are the decimeter wavelength type III and type-III-like bursts. Type IIIdm bursts have durations and drift rates that follow the same frequency dependence as meter wavelength type III bursts. Other than the fact that type IIIdm bursts occur lower in the corona in a higher density environment ($n_e \sim 10^{15}$–10^{16} m^{-3}), an important difference between meter wavelength type III and type IIIdm bursts is in the sense of frequency drift. The bulk (∼90%) of type IIIdm bursts drift from low to high frequencies, implying that they are excited by downward-directed electron beams. Roughly half of these reverse-slope type IIIdm bursts are correlated with impulsive hard x-ray (HXR) emission. Studies of strong flares show that a detailed correspondence exists between type III, reverse-slope type IIIdm, or type III–reverse-slope type IIIdm pairs and discrete HXR pulses in flares. This is taken to be strong evidence that bidirectional beams of electrons are produced during the impulsive phase of flares. The upward directed beams can produce decimeter and meter wavelength type III bursts (or type J and type U bursts in large-scale, closed magnetic loops) while downward-directed beams can produce type IIIdm and/or HXR pulses via thick-target bremsstrahlung emission in the chromosphere.

Bursts at centimeter and millimeter wavelengths

Bursts at centimeter wavelength accompany flares of all sizes. Electrons are commonly accelerated to energies of several ×100 keV during the impulsive phase on a timescale of seconds. These electrons are injected

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

into coronal magnetic loops where they emit incoherent gyrosynchrotron emission. The spectral maximum of gyrosynchrotron emission is typically in the range of 5–10 GHz ($\lambda \approx$ 3–6 cm). The low-frequency ($\nu \lesssim$ 5 GHz) source is therefore optically thick while the high-frequency ($\nu \gtrsim$ 10 GHz) source is optically thin. The morphology of a radio burst depends on the details of the energy distribution of energetic electrons, on the magnetic field configuration and on the ambient plasma. At low frequencies the entire radio source, defined by those coronal magnetic loops to which energetic electrons have access, is typically optically thick. The optical depth of the emission strongly depends on the magnetic field strength. Since the footpoints of a given coronal magnetic loop are more strongly magnetized than the loop top, footpoint emission dominates in optically thin sources (figure 1).

Radio bursts are highly dynamic. Time sequences of images of the evolving radio source show that, as the number of energetic electrons in the source increases with time, parts of the source change from being optically thin to optically thick. The radio source morphology can also vary as the magnetic connectivity between coronal loops changes in time. As a consequence of optical depth effects and/or changes in the magnetic topology, the morphology, flux and polarization of radio sources can change radically as a function of time and frequency. Figure 2 shows an example of an observation made by the Very Large Array at 4.9 GHz (λ = 6.1 cm) compared with the underlying chromospheric Hα emission. The Hα ribbons of emission demarcate the footpoints of an arcade of magnetic loops. Early in the event, footpoint emission is seen. Later, the Hα ribbons are bridged, the radio source becomes optically thick and the source maximum lies between the magnetic footpoints.

Flares are commonly accompanied by millimeter wavelength emission. Radiation at millimeter wavelengths is of particular interest because, when due to gyrosynchrotron emission, it is produced by electrons with energies of a few MeV. Hence, millimeter wavelength observations offer access to some of the most energetic electrons accelerated in flares, those which are also responsible for electron bremsstrahlung γ-ray emission (see SOLAR FLARES: GAMMA RAYS). Fixed-frequency observations of the spatially integrated flux from flares with polarimeters show that many have an apparent spectral flattening at millimeter wavelengths. Most impulsive flares show evidence for a post-burst increase in flux due to optically thin, thermal free–free emission from warm plasma ablated from the chromosphere by nonthermal electrons. This may account for the spectral flattening in some bursts. Other flares, however, clearly involve a distinct population of nonthermal electrons at high energies, separate from that producing centimeter wavelength and HXR radiation, and due, perhaps, to an additional acceleration mechanism or mechanisms. Spectral hardening at high energies has also been noted in photon spectra observed by spectrometers on board the Solar Maximum Mission, Hinotori and GRANAT satellites. Joint millimeter wavelength–γ-ray observations have confirmed that at least some flares clearly show the presence of a distinct, hard, nonthermal component of energetic electrons.

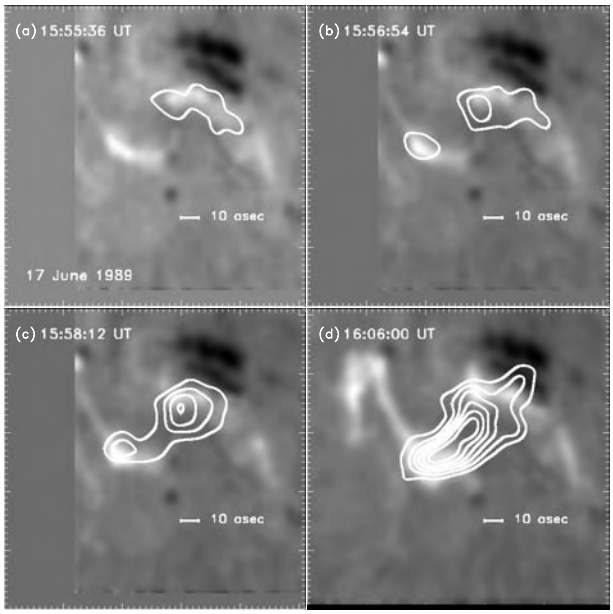

Figure 2. Example of the time evolution of a flaring source observed by the Very Large Array at 4.9 GHz (λ = 6.1 cm; contours) on 17 June 1989. The grayscale shows the underlying Hα emission.

Relation between radio and x-ray bursts

The fact that time profiles of centimeter wavelength and HXR emission are quite similar during flares was recognized long ago, as was the correlation between flux levels in the two emissions. The close correlation between centimeter wavelength and HXR emission during flares has often been cited as evidence that the 'same' population of energetic electrons is responsible for both types of emission. Comparisons of HXR and centimeter wavelength bursts have established that this is essentially the case to the extent that the HXR- and centimeter-wavelength-emitting electrons are drawn from the same nonthermal distribution of electrons. Centimeter-wavelength-emitting electrons tend to be of higher energy than the electrons responsible for 30–100 keV HXR emission. For impulsive flares, electrons with energies of order a few $\times$100 keV gyrating in magnetic fields of 300–900 G are typically responsible for centimeter wavelength emission. In long-duration events, higher-energy electrons ($\sim$1 MeV) gyrating in weaker magnetic fields ($\leq$100 G) are responsible for the observed centimeter wavelength emission (see SOLAR FLARE CLASSIFICATION).

While there is often a close correlation between HXR and centimeter wavelength emission flux and time variation, they differ in detail. Timing comparisons made with spatially unresolved HXR counting rates and

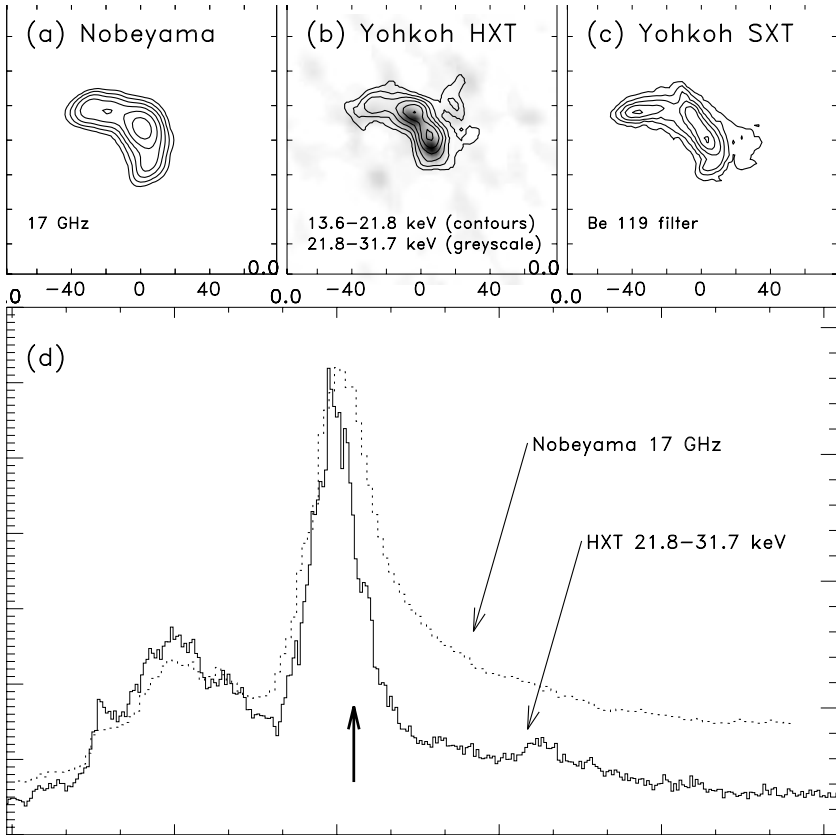

Figure 3. Observations of a flare by the Nobeyama radioheliograph and Yohkoh. (*a*) A snapshot map of the 17 GHz source. (*b*) Snapshot maps of the 13.9–22.7 keV (contours) and the 22.7–32.7 keV (grayscale) emission. (*c*) A snapshot of the SXR emission. (*d*) Time variation of the total 17 GHz flux and the 22.7–32.7 keV HXR counts. The time of the images shown in (*a*), (*b*) and (*c*) is indicated by a vertical arrow. Note the delay of the 17 GHz maximum relative to that in HXRs and the more extended decay.

radio fluxes find that temporal features in centimeter wavelength emission (e.g. the time of maximum flux) lag those in HXRs by up to a few seconds. Furthermore, the centimeter wavelength emission typically decays more slowly than the HXR count rate (figure 3). While transport effects might be relevant to the smallest delays observed, electron trapping may account for the full range of delays observed. Electron trapping is a result of electrons being injected into a magnetic field topology that converges near the base of the corona. Only those electrons with trajectories at sufficiently small angles relative to the local magnetic field vector (the pitch angle) can escape, or precipitate, from the trap. The cone of pitch angles that enable electrons to escape from the trap is called the loss cone. Various mechanisms can scatter electrons into the loss cone, including collisions of the energetic electrons with background electrons and ions (Coulomb collisions) or scattering on a spectrum of waves (e.g. whistler-mode waves). In the case of Coulomb collisions, high-energy electrons have a longer lifetime against scattering into the loss cone than low-energy electrons and therefore remain in the magnetic trap for a longer time. Consequently the radiation they emit peaks later and decays more slowly than emission from lower-energy electrons. Another possible reason for the delay between centimeter wavelength and HXR emission is that higher-energy electrons are simply accelerated somewhat later than lower-energy electrons in a 'second-step' process such as stochastic acceleration.

The spatial relationship between centimeter wavelength and x-ray bursts has recently been clarified. Soft x-ray (SXR) emission demarcates coronal magnetic loops containing hot, dense, thermal plasma. The dominant sources of HXR emission are in conjugate magnetic footpoints in the upper chromosphere and low corona where nonthermal electrons impact dense, relatively cool material and produce thick-target bremsstrahlung radiation. Centimeter wavelength emission traces out the entire volume accessible to nonthermal electrons. Hence, the optically thick emission defines its spatial extent. At frequencies where the centimeter wavelength emission is optically thin, regions characterized by strong magnetic fields dominate, e.g. magnetic footpoints. Recent studies indicate that, in asymmetric magnetic loops, HXR emission is emitted preferentially from the magnetically weaker footpoint, where electrons precipitate from the

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

trap in greater numbers, while centimeter wavelength emission is stronger in the magnetically stronger footpoint, leading to a spatial displacement between the dominant HXR and centimeter wavelength sources. Recent studies of centimeter wavelength and HXR source morphologies suggest that impulsive flares commonly involve loop–loop interactions—both a compact and a larger-scale magnetic loop structure interact owing to new flux emerging into pre-existing magnetic structures. Magnetic cusp morphologies also appear to play an important role in flares (see SOLAR WIND: ENERGETIC PARTICLES).

Radio bursts as diagnostics of physical processes

Both low- and high-frequency radio bursts offer diagnostics of a variety of physical parameters and processes during flares. The multitudes of type IIIdm bursts that accompany impulsive flares yield insight into the nature of energy release. With each type-III-like event corresponding to a discrete electron energization event, studies of the temporal and spatial distribution of type IIIdm bursts offer a means of constraining local conditions in the energy release site and the means by which energy release proceeds. Recent work in this area has concentrated on 'avalanche' models of flares, wherein the fragmentary nature of energy release plays a central role.

High-frequency bursts also yield insights into local conditions in the flaring source and into electron acceleration and transport. Unlike HXR emission, gyrosynchrotron emission has a sensitive dependence on the magnetic field strength and orientation in the source. Spatially and temporally resolved spectral observations offer a means of constraining the magnetic field in the flaring source. Such observations also allow the electron distribution function to be measured as a function of space and time. Current research is directed toward making such measurements in order to clarify which, of the many possible, electron acceleration mechanisms operates during flares—quasi-static dc electric fields, weak double layers, stochastic acceleration or shocks—and under what circumstances (see SOLAR FLARES: PARTICLE ACCELERATION MECHANISMS). Similarly, the details of the evolution of the emitted spectrum of radiation shed light on the transport of electrons throughout the flaring volume: the details of electron trapping, electron scattering, electron precipitation and chromospheric ablation.

Solar Flares: Relation to Coronal Mass Ejections

SOLAR FLARES and SOLAR CORONAL MASS EJECTIONS have both been associated with geomagnetic activity such as the AURORA, radio interference and 'geomagnetic storms' caused by large currents flowing through the Earth's magnetosphere. They are also both associated with high fluxes of energetic particles ('proton events') in near-Earth space. However, they are different types of event.

Solar flares are sudden, intense increases in brightness of particular solar features. They have been observed for over a century in visible light, and are detectable with radio telescopes. With the advent of space-based observations, flares have been observed throughout the short end of the electromagnetic spectrum, from ultraviolet through to gamma rays. Flares occur when small, intense regions of the solar magnetic field undergo reorganization, suddenly releasing energy into the solar coronal and chromospheric plasma. In the near-Earth space environment, flares cause immediate increases in the flux of ionizing radiation such as highly energetic electrons (β rays), protons and photons (γ rays). They are also correlated with delayed geomagnetic effects at Earth: the aurora and temporary motion of the Earth's magnetic field are more likely to be observed three days after a solar flare than at other times. This delay time corresponds to the transit time of the slow SOLAR WIND that propagates out from the Sun at $\sim$400 km s^{-1}. However, not all flares are associated with aurorae or geomagnetic storms; and some aurorae occur even without a precursor solar flare.

Coronal mass ejections (CMEs) are eruptions of large, massive bodies of plasma from the corona. CMEs can span 120° of solar latitude or longitude, and involve up to 10^{16} grams (10^{10} metric tons). They have been discovered only since the advent of the CORONAGRAPH, and have been studied in detail only since the advent of SKYLAB and other space-based coronagraphs such as the Solar Maximum Mission coronagraph and, more recently, the LASCO coronagraph aboard the SOHO spacecraft. Coronal mass ejections are correlated with flares, but appear to be more closely associated with the lift-off of FILAMENTS from the surface of the Sun. Because only half of the solar surface is visible at any one time, half of all CMEs originate on the far side of the Sun. Approximately half of the observed CMEs can be traced to the disappearance of a filament or prominence on the visible disk of the Sun; these statistics indicate that all CMEs originate from filaments. High resolution ultraviolet image sequences from the Transition Region and Coronal Explorer (TRACE) satellite and from the SOHO/EIT instrument have shown that filament 'lift-off' is central to the formation of CMEs.

The association between flares and CMEs is not coincidental. Coronal mass ejections appear to be caused by large-scale instabilities in magnetic structures (filaments) up to 300 000 km in size, while flares are caused by smaller scale instabilities that cause sudden reconnection of field lines within very small (<1000 km) volumes. Filamentary lift-off, and its associated field reorganization, causes additional local stress in the magnetic field, which may sometimes trigger a flare; and flaring causes field reconfigurations that can trigger large scale instabilities. Which (if either) of these mechanisms is correct is currently unknown.

Solar Flares: White Light

Characteristics of white light solar flares

A white light flare is a short-lived increase of the solar continuum emission, with a duration of 1–10 min, that takes place during some solar FLARES. The first white light flare was detected by Carrington in 1859 as a local and short-duration brightening on a white light picture of the Sun. Since spectral observations indicate that the continuum emission enhancement extends towards the UV part of the spectrum, the term 'White light flare' means more generally an enhancement of the continuum spectrum.

There is no world-wide flare patrol organization to record flares in white light such as exists for recording flares in the hydrogen Hα line. Consequently, white light flares appear as events rarer than they presumably are, and only about a hundred of them (fewer than 90 in 1993) have been reported.

The typical appearance of the spatial distribution of the white light emission is one, two or sometimes more bright patches. The white light brightenings are most of the time moving very fast or jumping from point to point. Some observations made with a passband filter centered at 4308 Å displayed a double footpoint character, suggesting that the white light flares observed were located at the base of magnetic flux tubes (see also SOLAR PHOTOSPHERIC MAGNETIC FLUX TUBES: OBSERVATIONS).

Filtergram measurements, made with broad-band FILTERS, are affected by the enhancement of the intensities and of the number of the atomic lines that occurs during the flare process. This enhancement is particularly high in the blue part of the spectrum. Intensities up to twice the quiet Sun continuum intensity in the visible have then been reported using filters, when the continuum intensity enhancements measured on the spectrum did not exceed 10–20%. Spectral observations of white light flares, when not made with broad-band filters, require the spectrograph slit to be located at the right position and at the right time. Therefore, the wavelength intensity spectra of no more than a few tens of flares have been observed, making the physical origin of white light flares not yet fully understood.

Two extreme typical spectra have been reported in observed white light flare spectra. They differ by the presence or not, near 3646 Å, of a discontinuity of the continuum intensity. The presence of a discontinuity implies that the emission is hydrogen free–bound emission resulting from the recombination between a proton and an electron. At visible wavelengths, the main contribution comes from the Paschen continuum associated with recombination leaving the recombined electron on an energy level described by the main quantum number $n = 3$. Recombination to the level $n = 2$ produces Balmer continuum emission at wavelengths shorter than 3646 Å, introducing a discontinuity at this wavelength. Contrary to electron–proton recombination, recombination of electrons with neutral hydrogen atoms to form an H^- ion or modifications of the electron velocities in the field of this ion do not produce a discontinuity in the UV.

The two kinds of continuum emission, due respectively to hydrogen and H^-, originate from different depths in the solar atmosphere. The Balmer continuum is formed at the chromospheric level, while the H^- emission is formed deeper at the photospheric level where the local hydrogen and electron densities are higher. Therefore, the amplitude of the Balmer discontinuity provides information on the depth of formation of the white light flare emission, i.e. on the atmospheric layers from which the radiated energy originates.

It is widely accepted that solar flares come from the fast dissipation of magnetic energy, and most flare models put the location of this dissipation somewhere in the solar CORONA. This hypothesis has been supported by the possibility of explaining the main properties of chromospheric Hα flares by a transport of energy from the corona down to the lower atmosphere by various processes, such as particle beam propagation, heat conduction or irradiation. The total energy radiated in the excess of continuum emission of a white light flare can reach 10^{30} erg; this is comparable to the energy involved in chromospheric flares. Therefore, flare models must take into account the white light flare phenomenon.

The possibility of explaining white light flares by energy transport from the corona must be checked. This requires the estimation of the depth of formation of the observed continuum emission, in order to put constraints on the depth of penetration of the energy coming from coronal heights, and on the amount of energy that must be deposited in order to compensate for the radiative loss.

Origin of white light flares

Apart from local heating, the origin of white light flares was looked for in the few processes likely to deposit energy into the solar CHROMOSPHERE or high SOLAR PHOTOSPHERE, i.e. heat conduction, particle bombardment and radiative heating. The decrease of the thermal gradient with height suggests that the heat conduction flux is too low to explain white light flares, most of the heat flux being evacuated in UV lines in the transition zone between the corona and the chromosphere. The remaining energy transport processes are particle bombardment and radiative heating.

Electron bombardment is present in most energetic flares. It is detected via the bremsstrahlung hard x-ray emission associated with the change in the orientation of the velocity vector of energetic electrons in the electric field of the ions. During their propagation to the lower atmosphere, electrons also collide with local electrons and lose most of their energy—nearly five orders of magnitude more than in brehmsstrahlung emission—in these Coulomb collisions. The rate of deposition of energy by an electron beam at the maximum of hard x-ray emission can exceed 10^{11} erg cm^{-2} s^{-1} and be one order of magnitude higher than the rate of energy lost in the enhancement of the continuum emission.

The beam electrons lose their energy in inelastic collisions with electrons and in elastic and inelastic collisions with neutral hydrogen. The depth of penetration, expressed by the column mass m crossed by high-energy electrons, moving vertically, is related to their energy E_m by

$$E_m \approx \left(\frac{K' 2\pi e^4}{m_{\rm H}} m \right)^{1/2}$$

where $m_{\rm H}$ is the hydrogen atom mass and K' is a function of the target plasma degree of ionization and of various parameters describing the effect of collisions on the particle energy. Entering the numerical values of the constants, and expressing m in g cm^{-2} and E_m in keV, leads to $E_m \approx 1.25 \times 10^3 \; m^{1/2}$. Collisions with local electrons heat the upper part of the chromosphere to coronal temperatures and shift down the region of minimum temperature and the chromosphere. The formation of the hot 10^7 K coronal plasma is due to the lower part of the electron energy spectrum. For beams carrying a high energy flux, the electrons that penetrate to layers dense enough for their temperature to stay, after heating, below 10^4 K are those of energy higher than about 50 keV. Only electrons of about 120 keV penetrate down to the base of the preflare chromospheric plateau, at m equal to 0.01 g cm^{-2}.

Inelastic collisions with neutral hydrogen, by increasing the hydrogen ionization rate by four to six orders of magnitude, increase accordingly the recombination rate and consequently lead, in the heated and deeper chromosphere, to an enhancement of both the bound–free Paschen and Balmer continua. Prediction of the resulting continuum emission requires us to compute the depth variation of temperature and density that results from beam bombardment.

Depending on the amplitude of the particle energy flux, chromospheric condensations may or may not be generated. They are formed in explosive chromospheric heating, i.e. when the heating rate of the chromospheric plasma is beyond its ability to radiate, leading to a very rapid temperature increase (see also CHROMOSPHERE: HEATING MECHANISM). If the time scale for this temperature change is shorter than the hydrodynamic expansion time, a strong pressure increase follows that drives matter both upward and downward. The compression of the plasma below increases its density. That, in turn, leads to a decrease of its temperature in order to reduce its radiative loss. A chromospheric condensation moving downward is formed, with higher density and lower temperature than the surrounding atmosphere, and such condensation was suggested to be at the origin of white light flares.

Computations of the white light emission of chromospheric condensations have been limited to empirical models, where the temperature and density of the condensation were prescribed. These computations showed that an increase of the white light continuum intensity requires the condensation to be hotter than its surroundings, while dynamical models of the response of the atmosphere to beam bombardment lead to a condensation cooler than its surroundings.

Observations of white light flares during hard x-ray emission in the absence of chromospheric condensation have been reported. In a flaring ACTIVE REGION, the presence of electron bombardment was established by the characteristic shape of the Hα line profiles that exhibited a strong self-reversal of the emission core. The selected locations, where this signature was the strongest, did not show the typical asymmetry due to the depth dependent Doppler redshift, that results from the downward motion of chromospheric condensations. However, they were associated with a strong enhancement of the white light continuum emission. This enhancement was not present at other locations that showed the signatures of chromospheric condensation.

Comparison of the time variation of the white light and hard x-ray flare continuum emission generally shows a good time correlation during the few minutes' duration of the impulsive phase (see SOLAR FLARES: IMPULSIVE PHASE). Since hard x-ray emission is measured without any spatial resolution, comparison is made between the total hard x-ray power of an unresolved hard x-ray source and the white light flare intensity at the location of maximum brightness. The total power deposited into the solar atmosphere by an electron beam, the electron energy flux, and the resulting white light flare intensity, depends on the beam cross section. Therefore, not all hard x-ray power peaks are expected to be associated with white light flare emission.

The overall time correlation between white light and hard x-ray emission varies with the hard x-ray photon energy. On average, a good time correlation is found, that increases with the photon energy. Time delays of the white light flare emission peak relative to the hard x-ray power peak above 50 keV, close to the observation time resolution of about 1 s, were observed. Indeed, this strongly suggests that energetic electrons bombarding the solar atmosphere are at the origin of the observed white light emission.

Impulsive hard x-ray emission lasts only a few minutes and is generally followed by a more gradual rise and fall of the soft x-ray emission coming from the hot plasma generated presumably by electron bombardment. White light flare emission has been reported to continue during this gradual phase and to peak at the time of maximum of the 10 keV soft x-ray emission. Therefore, heating of the lower atmosphere by soft x-ray photons was proposed as the origin of the gradual phase of white light flares.

For an event observed on 1 July 1980 the soft x-ray peak power was within a factor two of the white light power, supporting the hypothesis of soft X-ray irradiation as at the origin of the progressive phase of white light flare emission. In other events, at the time of the peak of white light emission the power radiated over 2π by 1–8 Å soft x-ray photons was reported to be an order of magnitude smaller than the white light flare power. However, the assumption of isotropic emission in soft

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

x-rays, used in all comparisons, is not valid if the x-ray source is optically thin and not spherical. The x-ray intensity is then proportional to the extension of the soft x-ray source along the direction of photon propagation, and a source more extended in height that laterally would irradiate the lower atmosphere more than expected from measurements made in a direction other than vertical.

The wavelength dependence of white light emission provides additional constraints on white light flare models. The number of events for which simultaneous observations of the white light spectrum and of the hard x-ray emission are available is still very limited. However, it has been reported that the wavelength spectrum of events for which a good time correlation between hard x-ray and white light flare emission is observed shows a significant Balmer jump, not observed in events for which there is no such time correlation.

Atmospheric heating by electron beams is not restrained to chromospheric layers and occurs also in the upper photospheric layers. At the higher hydrogen number density of the temperature minimum region, electron bombardment, via an increase in the electron number density, enhances the H^- number density. As a result, atmospheric backwarming by the enhanced chromospheric radiation takes place, increasing the temperature of the upper photosphere. As an example, a beam of electrons with an energy distribution of the energy flux, above a 70 keV low-energy cut-off, given by a power law, carrying an energy flux of about 8×10^{10} erg cm^{-2} s^{-1}, produces a temperature rise of 240 K at the temperature minimum. Consequently, the intensity of the H^- white light continuum emission increases, which adds a significant contribution to the chromospheric hydrogen free–bound emission and reduces the amplitude of the Balmer jump. However, even when reduced in amplitude the Balmer discontinuity is still expected to be present in the spectrum.

In a very few observed spectra, the Balmer discontinuity is not present at all. Therefore, soft x-ray irradiation has been proposed as possibly releasing energy deep enough in the solar atmosphere to generate a dominant H^- continuum emission. Such a model requires that most of the x-ray energy is deposited deep enough in the solar atmosphere, at a column mass higher than 0.1 g cm^{-2}. 10 keV photons satisfy this condition. As reported above, the observational checks of the validity of this hypothesis are still contradictory.

Like electron beams, proton beams deposit energy in the solar atmosphere. The ratio of proton and electron energy needed to reach a given atmospheric depth is the square root of their mass ratio. Consequently, protons must have an energy higher than about 150 keV at the beginning of the flare to interact with the chromosphere, with an energy requirement increasing to the MeV range with the downward shift of the chromosphere that occurs during the flare. Above about 1.5 MeV, protons can be detected via the gamma ray lines they produce (see also SOLAR FLARES: GAMMA RAYS). Below this limit they are not detectable, except by measurements of the linear polarization in chromospheric lines, like the hydrogen Hα line, that they generate by impact.

By non-thermal ionization of the background hydrogen, protons could generate white light continuum emission. The resulting white light flare would be time correlated with the evolution of the hot, soft x-ray emitting thermal plasma resulting from their bombardment. Depending on the proton beam characteristics, the power radiated in the white light flare could be higher than that radiated in soft x-rays. There will be no associated hard x-ray emission.

In conclusion, in the limit of the accuracy of existing measurements, energy transfer from coronal heights down to the low atmosphere, either by energetic particles or by energetic soft x-ray photons, is able to explain the white light flare characteristics without requiring *in situ* energy deposition. However, white light flare characteristics depend on the energy transport processes, which could be either particle bombardment or x-ray irradiation, and on their characteristics. Consequently, observations made from UV to infra-red, in hard and soft x-rays, with high space and time resolution, are still needed in order to progress in our understanding of the white light flares.

Solar Interior

The interior of the Sun is hidden from our sight, because it is opaque to electromagnetic waves: the radiation we receive from it on Earth is emitted in the outermost layers. Our knowledge of the solar interior is based solely on *theoretical models* which are built with some assumptions about the physical conditions and processes that are likely to prevail there, and on *helioseismology*, a very powerful technique which permits us to explore the interior directly with acoustic waves.

General properties

Until recently, all that we knew about the Sun came from observing it in visible light (see SUN: BASIC PROPERTIES). Its distance and radius $R_\odot$ were determined long ago by triangulation of the solar system, although the precision was increased significantly by using the modern technique of radar echoes. In the early nineteenth century, spectroscopy of the solar light revealed the gaseous nature of the emitting layers and the presence of many chemical elements known on Earth, with the notable exception of helium, which was detected on the Sun before it was discovered on Earth. Later, with the advent of atomic physics, it became possible to decipher the spectral lines, and to assess the temperature and composition of the surface layers (see SOLAR SPECTROSCOPY AND DIAGNOSTICS): hydrogen turned out to be most abundant species, followed by helium (≈25% in mass), the other elements representing only 2% altogether. The mass of the Sun, $M_\odot$, is deduced from the orbital motions of the planets and from precise laboratory measurements of the gravitational attraction between two bodies. Finally, the heat flux received on Earth gives the total amount of thermal energy radiated by the Sun into space, i.e. its luminosity $L_\odot$ (see SOLAR IRRADIANCE).

With a few 'reasonable' assumptions, these global parameters permit us to derive some important properties of the solar interior.

Central temperature

The first of these assumptions is that of *hydrostatic equilibrium*, which states that everywhere in the solar interior there is an exact balance between gravity and the pressure forces. This allows us to evaluate the central pressure, which is the weight of a column of matter of unit area; it is given by $P_c = \overline{\rho}\,\overline{g} R_\odot$ where $\overline{\rho}$ and $\overline{g}$ are suitable averages of the density and the gravity along the radius. As crude estimates, one may take the median value of all the quantities involved:

$$\overline{\rho} \approx \frac{\rho_c}{2} \qquad \overline{g} \approx \mathcal{G}\frac{M_\odot/2}{(R_\odot/2)^2}$$

with ρ_c being the central density and $\mathcal{G}$ the gravitational constant, which leads to

$$P_c \approx \rho_c \frac{\mathcal{G}M_\odot}{R_\odot}.$$

One may further assume that the solar material consists mostly of ionized hydrogen, as suggested by its surface composition, the molecular mass thus being $\mu = 0.5$ g, and that it obeys the perfect gas law $P = \mathcal{R}\rho T/\mu$, with $\mathcal{R}$ being the gas constant. This yields an estimate of the *central temperature* which depends only on the mass and the radius:

$$T_{\text{central}} \approx \frac{\mu}{\mathcal{R}}\frac{\mathcal{G}M_\odot}{R_\odot} \approx 10^7 \text{ K} \qquad (1)$$

a crude figure which is not that far from the value predicted by the best models of the present Sun.

Heat transport

This high temperature, compared with that of the surface layers (see SOLAR PHOTOSPHERE) whose effective temperature is $T_{\text{eff}} \approx 6000$ K, tells us that the thermal energy radiated into space is produced in the deep interior. One way to transport this energy to the surface is by radiation: the photons travel a short distance, are either scattered in another direction, or absorbed and re-emitted, and so on, until they finally reach the outermost layers from which they escape. Their mean-free path is small enough to guarantee that the solar interior is locally in *thermal equilibrium* and thus that the radiation is close to that of the ideal black body, meaning that the energy density only depends on temperature, and that it scales as T^4. This allows us to estimate the *optical thickness* τ of the Sun along its radius

$$\tau \approx \left(\frac{T_{\text{central}}}{T_{\text{eff}}}\right)^4 \approx 10^{13}.$$

This huge figure indicates that the Sun is extremely opaque: on the average, the mean free path of a photon is of order $R_\odot/\tau \approx 10^{-2}$ cm.

If it did not interact so strongly with matter, a photon emitted in the central region would cross the Sun in 2 s, but this very opaque medium forces it into a random walk: instead of τ interactions with matter, it will undergo τ^2 and therefore it will take τ times longer to escape, which amounts to 10^6 years.

But closer inspection of the solar surface shows that it is the seat of turbulent motions which also contribute to the heat transport. Indeed, near the surface, where hydrogen and helium are partly ionized, the opacity is so high that the thermal stratification becomes unstable: a bubble of solar matter which is lifted there from its equilibrium position becomes lighter than its environment, and hence it continues to rise. This *convective instability* occurs whenever the temperature gradient exceeds a critical value, which is the adiabatic gradient (i.e. the gradient that would be experienced by the bubble if it did not exchange heat with the surrounding medium). The instability condition is called the Schwarzschild criterion; it is usually expressed in terms of logarithmic temperature gradients with respect to pressure:

$$\frac{\mathrm{d}\log T}{\mathrm{d}\log P} > \left(\frac{\partial \log T}{\partial \log P}\right)_{\text{adiabatic}} \text{ or in short } \nabla > \nabla_{\text{ad}}.$$

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

Detailed models indicate that this criterion is satisfied in the outer third of the Sun (in radius). This turbulent region is the cause of the various phenomena which characterize the solar activity. Unfortunately, the description of the convective motions is still in a very crude state, and it remains one of the weakest points of modeling the solar interior (see SOLAR INTERIOR: CONVECTION ZONE). The inner two-thirds of the Sun are in stable equilibrium, and there the thermal energy is transported by radiation.

The energy source

The source of solar energy long remained a puzzle. All energy sources which were considered in the nineteenth century predicted a life expectancy for the Sun which was much smaller than the estimated age of some rocks on Earth. The problem was solved only in the 1920s, as scientists became aware that nuclear reactions could provide the necessary energy. When hydrogen is transformed into helium, 0.7% of the mass is changed into energy, according to Einstein's formula $E = mc^2$. One can easily estimate the Sun's life expectancy $t_{\rm exp}$ by equating the rate at which energy is emitted with the total amount which is available:

$$t_{\rm exp} = 0.1 \times 0.007 M_\odot c^2 / L_\odot \approx 10^{10} \text{ years}$$

where we have assumed that only 1/10 of the solar material will be changed into energy, namely that which is located in the innermost region, where the temperature is high enough to sustain nuclear reactions. This figure is compatible with the age of the solar system, which is now determined by the precise radiochemistry of its oldest components which can be analysed, namely meteorites.

The specific nuclear reactions which are responsible for the energy release in the Sun were identified later. The main contribution comes from the p–p chain, which starts with the fusion of two protons into a nucleus of deuterium: $\mathrm{p} + \mathrm{p} \rightarrow^2 \mathrm{H} + \mathrm{e}^+ + \nu_e$. This reaction involves the weak interaction and therefore emits a neutrino; since it is very slow, it regulates the whole energy production process. Other reactions follow, until ^{4}He is produced (see SOLAR INTERIOR: ENERGY GENERATION).

The next step of nuclear burning would transform helium into carbon, but with an efficiency ten times less per unit mass processed. This explains why most stars are observed in the hydrogen burning phase, on the so-called main sequence.

The rate of production of nuclear energy in the solar interior is very sensitive to temperature, because the fusion of two nuclei can only occur when their electrostatic repulsion is overcome by their kinetic energy: the higher the temperature, the higher the release of nuclear energy. This has an important consequence: assume that for some reason the production of nuclear energy slightly increases; additional heat is then deposited in the outer layers, which for this reason expand, but through hydrostatic balance that increase in radius leads to a decrease of the central temperature (see equation (1)), which has the effect of reducing the nuclear reaction rate. This self-regulation ensures that main-sequence stars, such as the Sun, are in stable thermal equilibrium.

Modeling the solar interior

A stellar model describes the internal constitution of a star, namely its pressure and temperature stratification, and also its chemical composition, as a function of depth, at a given age (see SOLAR INTERIOR: STANDARD MODELS). Usually such models are based on the assumption of hydrostatic equilibrium, although small departures from it are easily accounted for. Most models also assume spherical symmetry, a simplification which is well justified for the Sun, where the rotation is so slow that the centrifugal force may indeed be neglected compared with gravity.

The conservation laws for mass, momentum and energy yield a differential system which is of fourth order in space and of first order in time. Four boundary conditions are available for the main dependent variables: the obvious $m = 0$ for the mass and $L = 0$ for the luminosity at center $r = 0$, with the pressure P and the temperature T at the surface being borrowed from an atmospheric model. This would be sufficient to build a model if the chemical composition were known at each depth, but it too must be calculated in a consistent way. For that purpose one has to add a set of n differential equations, of first order in time and second order in space, which follow the evolution of n chemical species under the effect of nuclear reactions and/or microscopic diffusion; the associated boundary conditions simply state that the flux of each species vanishes at center and surface. In the first stellar models built in the 1950s, one was able only to track the transformation of hydrogen into helium, but nowadays n is no longer limited by computer performance. Finally one has to provide an equation of state to express the pressure as a function of density, temperature and composition, $P = P(\rho, T, X_i)$, the nuclear energy production rate $\varepsilon = \varepsilon(\rho, T, X_i)$ and the opacity $\kappa = \kappa(\rho, T, X_i)$ which determines the temperature gradient in the radiative regions. The time integration of this differential system is started at an early stage, when the star is still entirely convective, with specified uniform composition.

The need to calibrate

Mathematically, the problem is well defined: the differential system is of order $4+2n$ in space with an equal number of imposed boundary conditions. Its numerical integration presents no fundamental difficulty. Thus it would seem that it suffices to run a stellar structure code with specified mass $M_\odot$ to the present age of the Sun in order to obtain an acceptable solar model. Such a model could then be validated by comparing the predicted radius and luminosity with the observed ones. This would indeed be the case if the initial composition were known with high precision and if the physical processes coming into play were all translated into perfect numerical

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

prescriptions. Unfortunately, these two conditions are not yet satisfied.

The abundance of helium determined by spectroscopy is rather inaccurate: most of its spectral lines are hard to interpret because they are produced in the chromosphere and in the corona, where there are large deviations from local thermodynamic equilibrium. Furthermore, what one needs to start the time integration is the initial abundance Y_0, which may depart significantly from the present one because helium, being heavier than hydrogen, may have settled below the observed layers. For this reason Y_0 is taken as an arbitrary parameter (chosen in some reasonable range), to be adjusted by comparing the model with the actual Sun.

Another major uncertainty arises from the poor description of the convective heat transport. The recipe which is still commonly used, for lack of something better, also involves an arbitrary parameter, which is the ratio α between the mean-free path of the convective eddies (the so-called mixing length) and the pressure scale height.

For these reasons, the time integration of the constitutive equations is started with trial values for the two parameters Y_0 and α, and the resulting radius and luminosity, at the age of the Sun, are compared with the actual values $R_\odot$ and $L_\odot$. This procedure is iterated until the calibration is judged satisfactory, considering the other uncertainties.

The standard model

The standard model may be defined as the model which uses the best physical data that are available (equation of state, opacities, nuclear reaction rates) and which agrees best with the observations, while including the minimum of physical processes to achieve this result. As the observational constraints become more severe, the standard model is bound to include physical processes which have been neglected before. At the time of writing, the last process implemented in the standard model was the microscopic diffusion of helium and the heavy elements in the radiation zone, and this addition was required by the helioseismic profiles which clearly indicated that helium has settled out of the convection zone (see below).

Probing the solar interior

Since the observed values of the solar luminosity and radius are needed to calibrate the initial helium abundance Y_0 and the mixing length parameter α, one has to use other means to check the accuracy of solar models. Indirect evidence can be gleaned from observing the properties of other stars, for which models have been built with the same prescriptions (see SOLAR–STELLAR CONNECTION). But fortunately we dispose of means which allow us to probe the solar interior directly.

Solar neutrinos

Unlike photons, neutrinos show extremely little interaction with matter and therefore most of those emitted by the fusion of hydrogen in the central region of the Sun escape and a very small fraction of these can be detected on Earth. Indeed, no fewer than six different experiments have measured the flux of solar neutrinos, thus proving that the solar energy arises from nuclear fusion (see NEUTRINOS). Originally, the expectation was that these experiments would provide precious constraints on the central conditions of the Sun. However, the measured flux turned out to be systematically smaller than that predicted by the standard model, by a margin which cannot be reconciled by adjusting the sensitive parameters; we shall see below that non-standard models do not fare much better, although they include additional physical processes (see below).

The reason for this discrepancy has been the matter of long-standing debate. Is it due to serious imperfections of the standard model? Or is there something wrong with the experiments and their interpretation, as suggested by the incompatibility of their results? Or is the observed deficit due to some unknown property of the neutrino, beyond the electroweak theory? Recent results obtained at SuperKamiokande seem to favor the latter explanation; their straightforward explanation is that neutrinos have a non-zero mass; the neutrinos emitted in the solar core would then oscillate between two states, of which only one is detected by the present experiments. Thus it is quite possible that in the not too distant future the neutrino flux can be used to probe the solar core.

Helioseismology

Fortunately another technique has been developed in the meantime for the same purpose of sounding the solar interior, and it has turned out to be extremely powerful: called helioseismology, it makes use of the elastic properties of the Sun which allow for the propagation of waves. The sound waves observed at the surface of the Sun penetrate to a depth which depends on their frequency and on their wavelength; through an appropriate treatment inspired by seismology on Earth, they reveal some properties of the layers which they traverse (see HELIOSEISMIC OBSERVATIONS and HELIOSEISMOLOGY THEORY).

The vertical profile of the sound velocity determined by this technique has now reached a precision of the order of 10^{-4}, thus calling for models built with at least the same numerical accuracy, and also for a refined evaluation of solar age. Helioseismology permits us to locate the base of the convection zone within a thousandth of the radius, and it proves unquestionably that helium has settled below it. The characteristics of high-degree modes allow us to evaluate the helium content of the convection zone. Moreover, the rotational splitting of the mode frequencies yields the internal rotation velocity of the Sun as a function of depth and latitude.

Rotation of the solar interior

Helioseismology has revealed that the angular velocity varies with latitude in the solar convection zone, the equator rotating faster than the poles as observed at the surface, but that it depends little on depth (see SOLAR INTERIOR: ROTATION). Deeper down, the radiation zone appears to rotate almost uniformly, with the possible exception of the innermost core. The shallow boundary layer between the two rotation regimes, which has been called the *tachocline*, is a region of strong vertical shear, and it certainly plays a crucial role in the generation of the toroidal component of the magnetic field (see SOLAR ACTIVITY).

Non-standard models

The present standard model fits the helioseismic data rather well: within a few thousandths, when comparing the observed and predicted sound velocities. Many solar physicists believe that this excellent agreement will further improve with better opacities, better nuclear reaction rates, some refinements of the equation of state and more accurate determinations of the chemical composition. However, there are some observations which call for the implementation, in the model, of additional physical processes which have been neglected until now.

One is the *depletion of lithium* with age which is observed in solar-type stars: the lithium abundance is 100 times higher at the surface of young stars of solar mass (members of the Pleiades cluster, for example) than it is in the Sun. The reason is certainly that this fragile element is destroyed inside the Sun by the nuclear reaction $^{7}\mathrm{Li+p}\rightarrow{}^{4}\mathrm{He+}{}^{4}\mathrm{He}$, but the temperature at the base of the convection zone is not high enough to explain such a large depletion. Therefore some mixing must occur within the radiation zone to carry lithium deeper down, and non-standard models have been built to account for this mixing (see the review by Pinsonneault 1997). Some invoke macoscopic motions, such as the large-scale flow which is induced by the spin-down of the star and the weak turbulence caused by the shear of differential rotation. Others ascribe this extra transport to the gravity waves which are emitted by the convective motions at the base of the convection zone.

Some mixing is also needed to soften the profile of molecular weight below the convection zone; microscopic diffusion and gravitational settling alone would establish a gradient whose steepness is incompatible with the helioseismic data. The fact that this mixing ought to occur in the strong shear of the tachocline is hardly a coincidence.

Non-standard models are also required to correctly predict the observed *internal rotation* of the Sun: in particular, they have to explain why the radiative interior appears to rotate so slowly and so uniformly. Before this property was established by helioseismology, the solar core was expected to rotate faster than the convective envelope, which is spun down by the solar wind. Magnetic torques can easily achieve that uniform rotation, but other mechanisms may also contribute, such as the transport of angular momentum by gravity waves.

Other non-standard models have been built to produce a smaller flux of neutrinos, in an effort to match the observed values; in general they introduce some extra mixing in the solar core, which modifies chemical composition and therefore the network of nuclear reactions and the emission of neutrinos. But so far these models have failed to comply with the helioseismic constraints. Work progresses very actively on such non-standard models.

Solar Interior: Convection Theory

Convection is the transport of energy by hot fluid moving upwards and cold fluid moving downwards. A familiar example is the upwards and downwards motions one may observe (best just before the boiling point) when heating water in a casserole. In stars, convection is often responsible for transporting heat up to the visible surface, or for transporting heat away from the central parts of the star, where energy is being generated by nuclear processes.

Whether or not convection occurs in a certain region of a star depends on how transparent or opaque the region is to radiation. The transparency (or its inverse, the opacity) determines the temperature gradient necessary to transport the total stellar energy output; the stellar luminosity. If the temperature gradient exceeds a certain critical threshold (which depends on the detailed properties of the gas), then the gas is convectively unstable, and convective motions occur spontaneously. The convective motions assist in the transportation of the stellar luminosity towards the surface, where the energy is finally radiated away freely into space in the form of light.

In the Sun, conditions are such that convection is the dominant energy transport mechanism in the outer 30% (by radius), while there is no convective transport of energy associated with the energy-generating central region.

Convective motions are directly visible on the solar surface; energy-carrying scales give rise to a cellular brightness pattern called GRANULATION (sizes from a few hundred to several thousand km), while larger, more deeply rooted scales are visible as patterns of primarily horizontal motions called meso-granulation (up to about 10 000 km) and super-granulation (up to about 100 000 km) (see SOLAR PHOTOSPHERE: MESOGRANULATION; SUPERGRANULATION).

Density stratification

One of the most decisive conditions influencing the way convection in the Sun has to organize itself is the enormous range of mass densities in the SOLAR INTERIOR. Figure 1 shows the density and pressure stratification, illustrating that the density (pressure) increases by over ten (fourteen) orders of magnitude from the surface down to the center of the Sun, where nuclear processes are generating the energy.

Note that, even though the solar convection zone extends over only 30% of the radius, eight orders of magnitude of density change occur there. These eight orders of magnitude have again been split into half, to illustrate that the top four orders of magnitude of density change occur within only 3000 km of the surface (corresponding to about 4% of the radius). The reason why one order of magnitude of density (or pressure) change near the surface covers a much smaller depth interval than further down is that the density scale height, defined as $H_\rho = \mathrm{d}z/\mathrm{d}\ln\rho$, is roughly proportional to temperature, and the temperature increases with depth below the solar surface. (See also SOLAR INTERIOR: CONVECTION ZONE.)

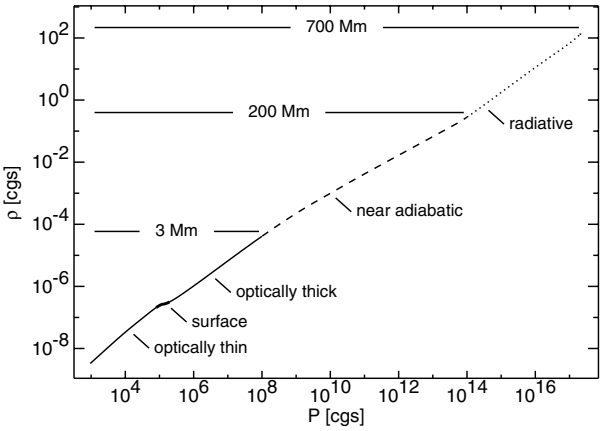

Figure 1. The density and pressure stratification of the Sun. The figure extends from the top of the photosphere to the center of the Sun. The properties of the thin transition region between the optically thin layers of the solar photosphere and the convection zone are crucial for the structure of the whole convection zone.

The small 'plateau' in the density marks the visible surface of the Sun. There, the temperature drops so rapidly that the density (which is roughly proportional to the pressure divided by the temperature) stays nearly constant, or even decreases slightly with depth. The pressure must necessarily increase monotonically with depth, since the pressure at any one depth is determined by the weight of all the mass at smaller depths (larger radii). But there is relatively little mass in the thin surface layer where the temperature drops rapidly (from about 10 000 K to about 5000 K over less than 100 km), and thus the pressure does not change much, and therefore the temperature drop is reflected in the density stratification as that little plateau.

The occurrence of that plateau, where the density scale height is radically different, and possibly even goes to infinity (this happens if the density has a local minimum there), may have significantly influenced the development of the theory of stellar convection. It was clear to researchers early on that the rapid change of density with depth must have important consequences for the flow patterns.

Consider, for example, two depth levels, where the vertical velocities are about the same, but the density differs by a factor of ten. The amount of matter transported upwards (as well as downwards) then is ten times larger through the deeper lying level, and all of the upward moving mass clearly cannot be accommodated by the higher lying level. The downward moving mass at that higher level, on the other hand, can easily be accommodated by the lower lying level, taking up only 10% of the downward mass transport capacity there. One concludes that most of the ascending gas from the lower lying level has to turn over into descending motion in between the two levels (thus making up the remaining 90% of downflow there).

It would then have been natural to incorporate the density scale height H_ρ, mentioned earlier, into a theoretical description of convection. However, because the density scale height may become infinite, whereas the pressure scale height by necessity is regular (while still being comparable to the density scale height where that is regular) one chose to instead use the pressure scale height as the geometrical scaling parameter of the theory.

The theory, that was developed for stellar convection by Erika Vitense (1953), thus has as one of its main ingredients the assumption that ascending hot gas must necessarily mix with descending, cooler gas over a distance that is roughly proportional to the pressure scale height, $H_P = \mathrm{d}z/\mathrm{d}\ln P$, which for an ideal gas is equal to $RT/g\mu$, where R is the gas constant, T is the temperature, g is the acceleration of gravity and μ is the mean molecular weight.

The distance over which mixing occurs is thus written as $\ell = \alpha H_P$, where α is a free parameter of the theory. In analogy with similar early theories for laboratory turbulence, the distance ℓ was called a 'mixing length', the parameter α was called the 'mixing length parameter', and the theory has been referred to as the 'mixing length theory'ever since.

Convective heat transport

Heat transport by convection occurs because upward moving gas, which is hotter, transports more energy upwards than cooler, downward moving gas transports downwards. The rate of convective energy transport, the convective energy flux, is therefore proportional to the product of the velocity amplitude and the amplitude of the temperature fluctuations. Pressure is roughly constant in horizontal planes, and one may thus invoke the specific heat capacity at constant pressure, C_P, and write the convective energy flux as

$$F_{\mathrm{conv}} \approx \langle \rho u_z C_P \Delta T \rangle \tag{1}$$

where u_z is the vertical velocity (positive upwards), and ΔT is the temperature fluctuation.

The convective instability occurs when vertical motions spontaneously generate positively correlated temperature and velocity perturbations. A parcel of gas that is displaced upwards expands and cools, because of the drop in pressure with height. The cooling is associated with adiabatic expansion, i.e. expansion without exchange of heat. Cooling by expansion is the process at work in a refrigerator, and the inverse, heating by compression, is the process at work in the cylinders of an engine (before ignition).

If the mean temperature drop with height is larger than the adiabatic cooling, then the displaced parcel finds itself hotter than the surroundings. Conversely, a downward displaced parcel of gas from above becomes cooler than the surroundings. Since hotter gas is lighter, and cooler gas is heavier, such perturbations are self-amplifying; the larger weight accelerates the cooler gas further downwards, while the lighter gas is accelerated upwards.

The mixing of ascending and descending gas mentioned earlier implies mixing of hot and cold gas, and mixing of upwards and downwards motions, and hence a loss of organized heat transport. It is the balance between the spontaneous growth associated with the convective instability and the loss associated with the mixing that ultimately determines the level at which convection saturates, for any given temperature gradient.

Balancing the loss of vertical momentum against the gain from the acceleration associated with the temperature difference ΔT one obtains the estimate

$$u_z^2 \sim \alpha_1 H_P g \Delta T / T \tag{2}$$

where g is the acceleration of gravity and α_1 is a parameter of the order of unity. Balancing the growth of temperature differences from vertical motions against the loss from mixing one obtains the estimate

$$\frac{\Delta T}{T} \sim \alpha_2 \left[\frac{\mathrm{d}\ln T}{\mathrm{d}\ln P} - \left(\frac{\mathrm{d}\ln T}{\mathrm{d}\ln P} \right)_{\mathrm{adiabatic}} \right] \tag{3}$$

where α_2 again is a parameter of the order of unity, and where the bracket is the difference between the actual temperature gradient and the one that corresponds to adiabatic expansion/contraction with height—this temperature gradient difference is often denoted $\Delta\nabla$.

When taken together, the equations above imply that the convective energy flux may be expected to scale roughly as

$$F_{\mathrm{conv}} \sim \alpha^{3/2} \rho c_s C_P T (\Delta\nabla)^{3/2} \tag{4}$$

where α is a parameter of the order of unity that satisfies $\alpha^{3/2} = \alpha_1^{1/2} \alpha_2 / \Gamma_1^{1/2}$, where Γ_1 is the adiabatic gas gamma, relating P/ρ to sound speed c_s. The quantity $\rho c_s C_P T$ has the dimension of an energy flux and in the interior of the Sun it is much larger than the actual solar energy flux. This means that the difference between the actual temperature gradient and the adiabatic one, $\Delta\nabla$, is small, and that consequently the relative temperature fluctuations $\Delta T/T$ and the ratio of velocity to sound speed v/c also are small.

One may therefore conclude that in the interior of the Sun convection is able to carry practically all of the required energy flux with relatively weak convective velocities, maintained by a temperature gradient that differs only little from the adiabatic one.

Close to the surface of the Sun this is no longer true; there the mass densities ρ, the sound speed c_s and the temperature T have all dropped so much that convective velocities reach a good fraction of the sound speed, the relative temperature fluctuations are large, and the temperature gradient deviates significantly from the adiabatic one.

Near-surface convection

The visible surface of the Sun occurs where the dimensionless optical depth τ_λ is equal to unity. The optical depth increment $\mathrm{d}\tau_\lambda$ is equal to $\rho\kappa_\lambda\,\mathrm{d}z$, so it is proportional to the mass density and the absorption coefficient κ_λ (that has dimension $\mathrm{m}^2\ \mathrm{kg}^{-1}$ in SI units). At temperatures of the order of the solar surface temperature, κ varies extremely rapidly with temperature ($\kappa \sim T^{10}$). In addition, a large number of atomic and molecular spectral lines also make the wavelength dependence of κ_λ very complicated.

The ultimate outcome of the decreasing efficiency of convective energy transport and the rapid decrease of opacity with decreasing temperature is that, near the solar surface, radiative energy transport again takes over as the dominant energy transport mechanism, after having turned over the responsibility for energy transport to convective motions in the solar convection zone. The transition occurs in an extremely narrow boundary layer, the thickness of which is significantly smaller than a pressure scale height, and much smaller than the horizontal size of the energy-carrying convection cells.

Because of the relatively low efficiency of convection in the crucial layers near the solar surface, the transition from predominantly convective to predominantly radiative energy transport is accompanied by a significant drop in entropy; there is a thin but very important superadiabatic layer that separates the optical surface of the Sun from the almost adiabatic interior. It is this layer that gives rise to the near-surface 'plateau' in density in figure 1, and it is also this layer that ultimately determines the radius of the Sun; if the entropy jump were different, the whole convection zone would have to adjust, so as to maintain the correct surface luminosity.

Numerical modeling

It is in practice impossible to determine the quantitative properties of the transition from convective to radiative convective energy transport by analytical means; there are too many, too complicated processes that interact.

There are two compounding reasons in particular that complicate the physics of the solar surface layers: on the one hand the optical properties, and on the other hand the very strong density and pressure stratification of the solar surface layers. The crucial transition from convective to radiative energy transport thus takes place inside convection cells, across a thin surface layer that is itself buckling and folding in response to local changes of the velocity and temperature patterns. At the same time, across a height extent of the order of characteristic horizontal scales of the energy carrying cells, the density varies by several orders of magnitude (cf figure 1).

Thus, whereas the scaling analysis leading to the 'mixing length' estimates above is useful to obtain order of magnitude estimates (and for many years have been used even for quantitative modeling, after 'calibrating' the mixing length parameter α empirically), one cannot hope to obtain self-consistent, parameter-free prediction without actually including all relevant physical processes in sufficient detail. For that, one must resort to accurate numerical modeling. (See NUMERICAL SIMULATION OF CONVECTION: COMPARISON WITH MIXING LENGTH THEORY.)

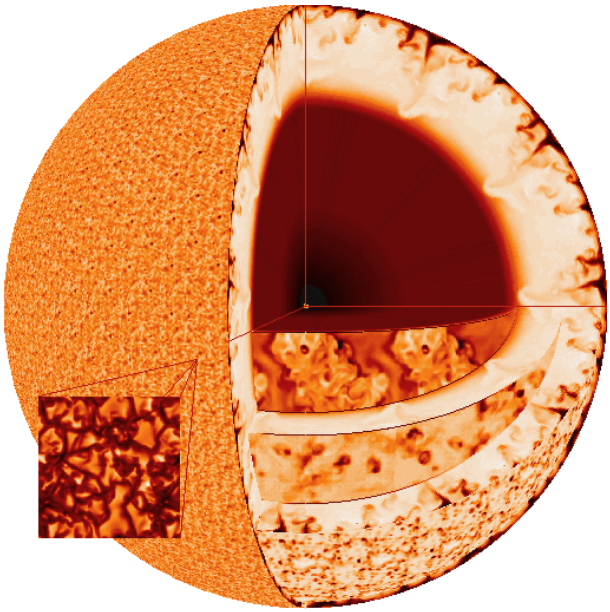

Figure 2. A composite illustration obtained by combining warped images from numerical simulations onto the faces of a cut-out view of the Sun. The quantity displayed is the entropy, which is almost constant in the convection zone, and is lower in the solar interior.

The circumstance that a shallow surface layer is almost all that matters, in so far as both observable surface properties and the influence of convection on the solar structure is concerned, is then indeed fortunate. It means that detailed 3D models may be restricted to a region only somewhat larger than that layer, thus avoiding most of the complications of covering multiple scales (in space and time). Also, for the very same reason that numerical modeling is really required, i.e. large-amplitude temperature fluctuations and ratios of velocity to sound speed v/c_s no longer small, fully compressible 3D simulations become feasible, because turn-over times are comparable to the sound travel times.

Deeper down, where the convective velocities are much smaller than the sound speed, and where the actual solar flux is much smaller than $\rho c_s C_P T$, direct numerical simulations are still prohibitively costly, because too many time steps are required to follow the slow motions. There, one may instead make scaled models that have convective fluxes much larger than the actual solar flux. From equations (2) and (4) one expects the velocity to scale as $v \sim F_{\mathrm{conv}}^{1/3}$, and the temperature to scale as $\delta T \sim F_{\mathrm{conv}}^{2/3}$. It is thus possible to rescale the results of such simulations to solar conditions. Properties such as the topology of the flow are expected to be invariant under such scalings.

Figure 2 shows results from such scaled models,

wrapped onto a spherical model of the Sun. Also shown is an inset with a blow-up of the surface radiation intensity of a model of the solar surface layers. Typical geometrical scales and evolution times in the surface model are a few thousand km, and a few minutes, respectively. The corresponding numbers for the lower part of the convection zone are of the order of a few hundred thousand km, and a few weeks, respectively. This illustrates why it is not possible to cover all geometrical scales and all time scales in a single numerical model. Nevertheless, numerical models are very helpful, both as a guide to the development of theoretical concepts, and as a source of synthetic observational data that may be compared in a direct, forward manner with observations.

Solar Interior: Convection Zone

The Sun, like all main sequence stars of moderate mass, possesses a deep convective envelope just below its surface in which turbulent fluid motions serve to carry outward the energy flux that results from nuclear burning within its core. Observations of the Sun reveal complex flows and magnetic structures that are evidence of highly turbulent convection just below the surface of this rotating star. Theoretical models of stellar structure and evolution indicate that such convection must extend from the surface well into the interior within the present Sun, forming a convection zone occupying about the outer 30% by radius (or a depth of nearly 200 Mm). Within this outer envelope, convective motions will transport nearly all of the emerging flux of energy, whereas below it radiation suffices to carry the flux outward from the core. The energy transport by fluid motion is very efficient throughout the convection zone, except in a thin superadiabatic boundary layer immediately beneath the photosphere in which there is a transition to transport by radiation in the solar atmosphere. There is another complex transition layer at the bottom of the zone where penetrative convective motions extend a small distance into the very stable radiative interior.

Intricate turbulent dynamics

Intense turbulence within the convection zone not only transports heat but also continually redistributes angular momentum. This leads to a pronounced DIFFERENTIAL ROTATION within the convection zone. It has long been known from observation of features such as SUNSPOTS that the surface of the Sun rotates differentially: there is a smooth poleward decline in the angular velocity Ω, the sidereal rotation period being about 25 days in equatorial regions and about 33 days near the poles. More recently, helioseismology has revealed how Ω varies with both radius and latitude throughout much of the solar interior. The convection also appears to build magnetic fields by some form of DYNAMO action, the details of which are likely to depend sensitively on the rotation profile that is established both within the convection zone and in a region of overshooting immediately beneath its base. Yet how the turbulence couples to the rotation and the magnetic field is not understood in detail. It is very difficult to describe theoretically the dynamics of such highly nonlinear compressible fluid flows that extend over many decades in scale. One of the novel aspects of such dynamics is that amidst the apparent chaos there also appears to be distinct order. This is suggested by the relatively smooth variation of angular velocity observed at the solar surface, and by the nearly cyclic temporal variation of magnetic activity, involving sunspot eruptions with very well defined rules for field parity and emergence latitudes as the cycle evolves.

The convection zone of the Sun thus exhibits some striking properties that have largely defied theoretical explanation. Most prominent are issues concerning its rotation profile with latitude and depth (the 'solar differential rotation problem'), and the manner in which the Sun achieves its 22-year cycles of magnetic activity ('solar dynamo problem'). Both global issues touch on the seeming inconsistency that turbulence can be both highly intermittent and chaotic on smaller spatial and temporal scales, and yet achieve a large-scale order that is robust in character. Observations of the solar surface show that the Sun possesses a wide range of scales of convection, ranging from granules ($\sim 10^3$ km or 1 Mm in horizontal size), to mesogranules ($\sim$5 Mm), to supergranules ($\sim$30 Mm), to possible patterns of giant cells comparable to the overall depth of that zone ($\sim$200 Mm) (see SOLAR PHOTOSPHERE: GRANULATION, SOLAR PHOTOSPHERE: MESOGRANULATION and SOLAR PHOTOSPHERE: SUPERGRANULATION). Similar scale separation is seen temporally. Small-scale magnetic fields rekindle with the turnover of the granulation ($\sim$10 min), and yet somehow the Sun achieves 22-year cycles of magnetic activity. The wide range of dynamical scales involved with turbulence in the Sun presents severe challenges to both theory and numerical simulation: in the convection zone of the Sun these scales range from about 10^5 km (about the depth of the convective layer) to 0.1 km or smaller (dissipation scales), encompassing at least six orders of magnitude for each physical dimension. The largest current turbulence simulations can capture about three orders of magnitude in each dimension. Theoretical progress in dealing with the turbulent dynamics of the solar convection zone thus requires trade-offs in either studying a highly turbulent but localized portion of a convecting spherical shell or a less turbulent but full shell with correct account of geometry.

The magnetic fields that emerge into the solar atmosphere are also diverse in character, and this must reflect how they are produced and shuffled within the depths of the convection zone. The cyclic eruption of strong magnetic fields through the solar surface in the form of sunspots and ACTIVE REGIONS has long been a center of attention. In the active Sun, large sunspots have central dark umbras with field strengths of 2000 to 3000 G and diameters as great as 10 Mm, surrounded by a brighter penumbra of up to three times that size. The largest of such active region complexes can span a good fraction of the disk. Yet observations have shown that magnetic flux is also emerging at a comparable rate during the quieter phases of the 22-year cycles, but does so through far smaller structures. In the quiet Sun, much of the magnetic energy resides in compact flux elements or tubes with strengths of the order of 1000 G to 1500 G, with these occupying only a very small fraction of the surface area to yield an average field strength of a few gauss. The smallest of the detected compact magnetic structures are the bright points, about 0.1 Mm in size, visible in the intergranular lanes. The magnetic fields also appear as somewhat larger structures, possibly composed of many individual flux tubes assembled into flux ropes that have broken through the solar surface, appearing as dark magnetic pores about 1 Mm across. Such strong field components in the quiet

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

Sun are augmented by a weaker component made up of many small dipole loop pairs with field strengths possibly as low as 50 G. The gradual sweeping of magnetic fields to mesogranule and supergranule boundaries yields an ordering of these fields into networks of larger scales, with such relatively narrow but widely spaced network lanes occupied by compact field elements.

Solar differential rotation

The advent of helioseismology, which involves the study of the acoustic p-mode oscillations of the solar interior that are observable at the surface, has permitted probing of both structure and dynamics below the solar surface. The profiles of angular velocity (Ω) revealed by helioseismology have turned out to be revolutionary, for they are unlike any anticipated by theory prior to such probing of the interior of a star. The convection in early numerical simulations of rotating convection in spherical shells was dominated by columnar roll-like cells (or 'banana cells') oriented in a north–south direction, the tilting of which yield nonlinear interactions or 'Reynolds stresses' that sustain the differential rotation. Such convection models yielded an angular velocity Ω nearly constant on cylinders, aligned with the rotation axis and decreasing with depth in the equatorial plane. The Sun does not appear to comply.

Helioseismology has shown that the rotation profiles obtained by inversion of frequency splittings of the *p* modes have a decidedly different character: the angular velocity observed near the surface, where the rotation is faster at the equator than near the poles, extends through much of the convection zone with little radial dependence. In particular, Ω at high latitudes in the convection zone appears to increase slowly with depth, at mid-latitudes it is nearly constant on radial lines, and near the equator it first increases and then gently decreases with depth. Another striking feature is the region of strong shear at the base of the convection zone, known as the *tachocline*, where Ω adjusts to apparent solid body rotation in the deeper radiative interior. Thus whereas the convection zone exhibits prominent differential rotation, the deep radiative interior does not; these two regions are joined by the complex shear of the tachocline. More detailed deductions about subsurface solar flows and rotation, and possible changes as the Sun enters active phases of its magnetic cycle, are becoming available from the nearly continuous helioseismic observations with the ground-based six-station Global Oscillation Network Group (GONG) project, and from the SOI–MDI experiment on the SOHO spacecraft.

Fully developed turbulence at Reynolds numbers R_e (ratio of inertial to viscous forces) of order 10^{12}, as estimated for the Sun, appears to redistribute angular momentum quite differently from what was thought on the basis of laminar and mildly turbulent convection studies, thereby yielding mean flows and rotation profiles of a special and different kind. Recent three-dimensional simulations have begun studying full spherical shells of rotating turbulent convection using spherical harmomics Y_ℓ^m (for horizontal expansion) up to degree $\ell \sim 400$. The models are a highly simplified description of the solar convection zone: solar values are taken for the heat flux, rotation rate, mass and radius, and a perfect gas is assumed since the upper boundary of the shell lies well below the H and He ionization zones. The computational domains include a region of stable stratification below the primary unstable zone in which the effects of penetrative convection can also be studied.

The resulting convection is highly time-dependent and the flows are intricate. The time-averaged angular velocity Ω is nearly constant on radial lines throughout much of the convection zone at mid latitudes, and there is a systematic decrease of rotation rate with latitude in going from the equator to the poles. The convection is now dominated by intermittent plumes of upflow and stronger downflow, some possessing a distinctive cyclonic swirl; the dominant role of coherent plumes is now becoming apparent. A tachocline at the base of the convection zone is not yet realized, since the simulations still operate at R_e where viscous coupling can imprint the local rotation rate of the unstable zone upon the stable region. The development of a tachocline may involve anisotropic diffusivities and confining magnetic fields. Some theoretical discussions concerning the tachocline invoke strong horizontal viscosity due to anisotropic turbulence in the stable layer to circumvent the diffusive spreading. Other models invoke magnetic fields to enforce solid body rotation in the radiative interior. Simulations at higher R_e (requiring greater resolution) and including the effects of magnetic fields can test such theories and provide hope for modeling the tachocline. It will be essential to have at least four-fold higher spatial resolution (effectively dealing with 2048^3 modes) in such simulations, now becoming feasible on the latest parallel machines, to study a fully developed convection zone bounded below by a radiative layer.

Solar dynamo and cyclic field emergence

Magnetic flux emergence (see SOLAR PHOTOSPHERIC MAGNETIC FLUX TUBES) at the solar photosphere occurs on a wide range of scales, from large active regions (sunspot groups) to small fibril concentrations in the intergranular lanes. A central problem of magnetic field generation in the Sun is the origin of the coherent magnetic field that emerges at the solar surface to form the active regions. Although it was once widely believed that all the smaller-scale flux was derived from the break-up of the larger regions, current observations suggest that flux emerges at a rate which is inconsistent with this simple fragmention model, and therefore flux must be actually generated at the smaller scales. The solar dynamo problem can thus be thought of as two problems rather than one, i.e. a *large-scale dynamo* responsible for global properties of the magnetic field including cyclic behavior and active regions, and a *small-scale dynamo*, contributing to the abundance of short-lived mixed-polarity flux found outside the active regions.

Dirac House, Temple Back, Bristol, BS1 6BE, UK

It is now commonly thought that the global dynamo behavior is derived from strong organized toroidal magnetic fields generated by the shearing flow of the tachocline just below the base of the solar convection zone. The weaker poloidal field is then regenerated throughout the convection zone by the action of cyclonic turbulence. This separation of the generation of toroidal field and the regeneration of poloidal field has been termed an *interface dynamo*. Recent *mean-field* dynamo models have shown that such an interface model can circumvent the problem of strong dynamo suppression feedback (α quenching) by mean magnetic fields and so produce field strengths similar to those inferred from observations. They can also give rise to modulation of the basic cycle and recurrent so-called grand minima.

The interface paradigm is based on a number of underlying processes, crucial to the overall operation of the dynamo, which are parametrized in mean-field models and yet should be modelled explicitly. The building blocks of the full mechanism are (a) the actual generation of field by cyclonic turbulence within the convection zone (small-scale dynamo, parametrized by the α effect in mean-field models), (b) turbulent transport of this field across the interface (enhanced turbulent diffusion in the mean-field sense), (c) its subsequent amplification by large-scale shear in the overshoot region below (large-scale dynamo, represented by the ω effect in mean-field models), and (d) transport of the resultant large-scale field through the convection zone to be either shredded and recycled or to emerge in the photosphere. Currently, computational resources are insufficient to model a complete system incorporating both small- and large-scale dynamo effects. Efforts are under way to study separately these individual building blocks, with the aim of using the intuition so developed toward attaining a fully nonlinear interface-type solar dynamo model as resources become available.

Solar Interior: Convection Zone Flux Tubes

The magnetic field at the solar surface reflects the presence of isolated flux tubes below the photosphere. The magnetic field is not diffusively distributed over the entire surface but is concentrated into regions of rather intense field, ranging from SUNSPOTS—with diameters of approximately 20 000 km and field strengths of 3000 G—down to smaller magnetic elements (100–200 km and 1000 G). The existence of this hierarchy of concentrated magnetic structures in the observable layers is indicative of the intermittent nature of magnetic fields in the underlying convection zone (see SOLAR INTERIOR: CONVECTION ZONE). The equilibrium and dynamics of flux tubes are basically different from those of a diffuse field. This has important consequences for the storage of magnetic flux, the onset and development of instabilities, the rise of magnetic flux towards the surface to form the observed active regions, and also for the understanding of the dynamo mechanism (see DYNAMO THEORY). Magnetic buoyancy due to the increased effective pressure inside the tubes poses a dilemma: on the one hand, it is necessary to bring the magnetic flux to the solar surface; on the other it leads to a rapid loss of magnetic flux from the convection zone, thus preventing the storage of magnetic flux long enough for the operation of a hydromagnetic dynamo. It is nowadays widely accepted that the magnetic field emerging at the surface is stored within a stable layer at the bottom of the convection zone prior to eruption.

Filamentary nature of the magnetic field

High-resolution observations show that the magnetic field at the surface of the Sun is not diffuse, but extremely concentrated into discrete structures in the form of magnetic flux tubes, of which sunspots are the most prominent manifestation (e.g. Zwaan 1992). More than 90% of the magnetic flux on the solar surface outside of sunspots and their associated active regions is concentrated into intense flux tubes (1–2 kG) of diameter 100–500 km. These small magnetic elements are surrounded by plasma with substantially lower field strength. This fibril state of the observed magnetic field is a consequence of the very large magnetic Reynolds number of the solar plasma and its unstable (superadiabatic) stratification in the layer below the photospheric surface. The idea that the discrete appearance of the magnetic field extends further through the convection zone is also supported by numerical simulations of magnetoconvection (see MAGNETOHYDRODYNAMICS: MAGNETOCONVECTION).

Apart from observations of the solar surface, there are indirect hints for the existence of a strong toroidal system of magnetic flux at the bottom of the solar convection zone or below. Bipolar active regions form by the emergence of large bundles of toroidal magnetic flux from the convection zone into the photosphere. In spite of the turbulent convection zone in which they are immersed, active regions show a large number of regularities (Moreno-Insertis 1994). For example, Hale's polarity rule, the tilt of active region's main axis (by typically 10°) with respect to the equator and the systematic asymmetry between the preceding and following parts of the active region (as regards morphology, stability and proper motion) point towards the presence of a strong toroidal magnetic field at the bottom of the convection zone or just below.

The concentration of magnetic flux into flux tubes has important consequences for its storage. Since a magnetic field gives rise to an effective 'magnetic pressure', a flux tube surrounded by almost field-free plasma can become buoyant. Buoyancy can be a very efficient mechanism in expelling magnetic flux to the solar surface. Some simplified estimates as well as detailed numerical simulations show that flux tubes with a field strength of the order of equipartition with the energy density of convective motions (or larger) rise to the solar surface within one month or less; this time scale is much shorter than the 11-year characteristic time for field generation and amplification by the dynamo process. In order to circumvent this problem, it has been suggested that most of the magnetic flux is stored within the overshoot layer, a slightly subadiabatically stratified layer below the convection zone proper.

Overshoot region

Overshooting is the penetration of convective motions from an unstable layer into an adjacent stable layer. The existence of convective penetration is known from both observation and experiment in the laboratory and in the Earth's atmosphere. A convective eddy is driven in the unstable region and arrives at the boundary of that region with some inertia sufficient to penetrate into the surrounding stable layers where it is decelerated by the stable stratification. This yields an enlargement of the region effectively mixed by convection.

Near the bottom of the solar convection zone, a steep gradient of the differential rotation profile can be inferred from helioseismological data (see HELIOSEISMIC OBSERVATIONS); this zone is called the 'solar tachocline'. Many astrophysicists think that this zone plays an important role in the mixing processes between the radiative and the convective zones. It could also be the principal source of solar magnetic flux. In order to investigate the problem of the storage of magnetic flux tubes in the overshoot region one exploits the fact that they are *thin* as compared with the local pressure scale-height.

Thin flux tubes

The study of the structure and dynamics of magnetic fields in stars is a complex mathematical problem due to the nonlinear nature of the magnetohydrodynamic (MHD) equations, to the presence of boundary layers and to the inhomogeneities involved. The filamentary nature of magnetic fields in the convection zone allows for a considerable simplification of the MHD equations.

The *thin flux-tube approximation* permits the reduction of the full set of MHD equations to a mathematically more tractable form without making any restriction on the compressibility of the plasma, the magnetic Lorentz force or gravity. In physical terms, the approximation amounts to assuming that the variation of the physical properties over the cross section of the tube is *small* as compared with the variation along it (with the exception of a jump at the boundary). Since for the stability and the first stages of the rise one is interested in perturbations that affect the flux tube as a whole, and given the large value of the pressure scale-height at the bottom of the convection zone (about 60 000 km), the use of the thin flux-tube approximation for the dynamics of the magnetic flux concentrations is perfectly justified.

With the aid of the thin flux tube approximation it is possible to obtain a consistent model of magnetic field storage, instability, dynamics and eruption not only for the Sun, but also for other stars with convection zones.

Stability of toroidal magnetic flux tubes

For a linear stability analysis of flux tubes in a stellar convection zone, one considers a toroidal flux tube symmetric with respect to the solar rotation axis and lying in a plane parallel to the equator, at an arbitrary latitude. Figure 1 shows a sketch of the adjustment of an initially buoyant flux tube with equal internal and external temperatures and angular velocities to a mechanical equilibrium characterized by neutral buoyancy and a longitudinal internal flow in the direction of stellar rotation: since the curvature force and the rotationally induced forces are both perpendicular to the axis of rotation, there always remains an unbalanced axial component of the buoyancy force (except for flux tubes lying exactly at the equatorial plane). Consequently, if the tube is to be at mechanical equilibrium, the matter inside the tube must be slightly cooler than its environment and rotate slightly faster. Since the motions causing the perturbation of the flux tube have a time-scale that is much shorter than the characteristic time for thermal relaxation, isentropic perturbations may be assumed (i.e. the entropy of each fluid element remains unchanged). Stability against isentropic perturbations can be examined by means of a normal-mode analysis of both axisymmetric and non-axisymmetric displacements of the equilibrium shape of the tube. The stability properties depend on the various parameters (e.g. latitude, field strength, superadiabaticity of the stratification, angular velocity and its gradients).

The stability analysis shows that the unstable stratification of the convection zone and the strong convective motions render the storage of magnetic flux in the convection zone proper impossible. The alternative is that the magnetic flux is stored in the overshoot layer underneath the convection zone, some 200 000 km below the solar surface, and with a thickness of only a fraction of the local pressure scale-height. Independent support for this idea comes from numerical simulations showing

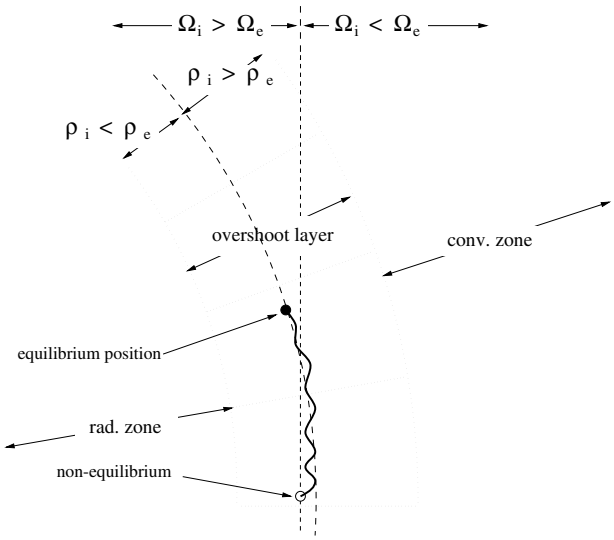

Figure 1. Approach of an initially buoyant flux tube (open circle) with $T_i = T_e$ and $\Omega_i = \Omega_e$ to a position of mechanical (force) equilibrium (full circle) characterized by neutral buoyancy ($\rho_i = \rho_e$) and faster internal rotation, $\Omega_i > \Omega_e$ (from Caligari *et al* 1998). Ω is angular velocity, ρ density, and T temperature. The subscripts 'i' and 'e' denote physical quantities inside and outside the flux tube, respectively.

that magnetic flux with a field strength of the order of the equipartition value is pumped downwards below the convection zone by the strong sinking plumes of overshooting convection.

Instability and rise of magnetic flux tubes

Due to the subadiabatic (stable) stratification of the overshoot layer, flux tubes can achieve a stable configuration in which buoyancy vanishes. Probably, the flux tubes evolve through a sequence of equilibria while being continuously amplified by the dynamo mechanism which is supposed to operate within this layer. Once the field has become sufficiently strong, instabilities set in; the most unstable perturbations (i.e. with the shortest growth time) are non-axisymmetric (i.e. undulatory) and give rise to the formation of rising loops. The critical magnetic field strength for the onset of the instability lies around 10^5 G for conditions prevailing at the bottom of the solar convection zone (e.g. Schüssler *et al* 1994). If we assume that a typical tube which later gives rise to an active region has a magnetic flux between 10^{21} and 10^{22} maxwell (i.e. at least the total flux of the active region), then the typical size of the tube at the onset of the instability must be of the order of 1000 km.

A linear stability analysis can provide the proper initial conditions for numerical simulations of the emergence of magnetic flux loops through the convection zone. Once an unstable loop has entered the superadiabatic part of the convection zone, the subsequent evolution becomes very fast and nonlinear, so that numerical simulations are necessary to follow its rise towards the surface. In the last two decades, the

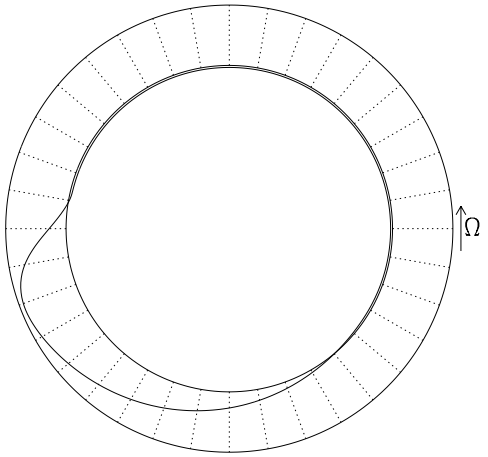

Figure 2. Snapshot of an unstable magnetic flux tube that started at the bottom of the convection zone. The direction of solar rotation is towards increasing azimuthal angle (from Caligari *et al* 1995).

nonlinear dynamic evolution of unstable flux tubes has been studied in detail by numerical integration of the thin flux-tube equations (see e.g. Schüssler *et al* 1994, Fisher *et al* 2000). For initial field strengths of the order of equipartition (10^4 G) or a few times this value, the Coriolis force plays a dominant role and flux tubes starting from low latitudes are deflected polewards along the solar rotation axis and emerge at unrealistically high latitudes, contrary to sunspot obervations. With a field strength of approximately 10^5 G, the results of the numerical simulations are in agreement with a number of observable features. For instance, the rise is not significantly deflected by the Coriolis force, so that the flux tubes emerge at low latitudes, the deviation of the eruption latitude from the starting latitude being less than 5°. Other features that are reproduced by the numerical simulations are the tilt angle (inclination with respect to the East–West direction) of sunspot groups or the asymmetry between the two legs of the rising tubes (figure 2).

Flux tubes and the dynamo problem

It is widely accepted that the solar activity cycle, with its various manifestations and regularities, is the result of a hydromagnetic dynamo operating at the bottom of the solar convection zone. The principle of dynamo action was first suggested by Larmor in 1919. Basically, it requires that the plasma moves in such a way as to induce electric currents capable of maintaining and amplifying a 'seed' field against Ohmic decay. In the case of stars like the Sun, one of the main ingredients for dynamo action is differential rotation, which generates the toroidal field component from the poloidal component. The generation of the poloidal field from the toroidal field is explained in terms of an induced electric current parallel to the mean magnetic field (α-effect), an idea originally put forward by Parker in the context of a turbulent solar dynamo.

The concentration of magnetic flux into intense tubes also has important consequences for the operation of the dynamo. The conventional kinematic approach—in which the back-reaction of the Lorentz force on the flow field is neglected and in which turbulent flows play a key role in regenerating the poloidal field from the toroidal component—is not applicable. Nevertheless, although the α-effect was originally formulated for rotating, turbulent convective systems, the basic idea behind Parker's topological argument is that the generation of an α-current is due to the lack of symmetry of the flow, and this can also be achieved by the combination of rotation and buoyancy instability. The picture of a dynamo working with strong (super-equipartition) fields without invoking convective turbulence has been outlined recently. In this dynamo model the flux tubes are stored in mechanical equilibrium in a layer of overshooting convection at the boundary with the radiative region. Differential rotation (or other mechanisms) intensifies the field strength until a critical value is reached above which buoyancy instabilities set in. The non-axisymmetric perturbations of the flux tubes combined with the Coriolis force give rise to helical waves of growing amplitude which produce an electric current in the direction of the mean ('unperturbed') magnetic field. The resulting α-effect is a 'dynamic' one in the sense that the Lorentz force and its feedback on the velocity field are taken into account (as well as the compressibility of the plasma). Only unstable, non-axisymmetric perturbations contribute to the mean electric current, which is antisymmetric with respect to the equator.

Conclusions and some open questions

From the properties of active regions it can be inferred that there must exist a strong toroidal flux system in the solar convection zone. Magnetic buoyancy poses a dilemma for the efficient operation of a hydromagnetic dynamo: on the one hand, it is necessary for flux emergence to take place, but on the other hand it is so efficient that it leads to a rapid flux loss from the convection zone. A way out from the dilemma is to assume that prior to eruption the magnetic field is stored in a stably stratified layer of convective penetration for a sufficiently long time for the dynamo to operate on it. Whether this storage is already in the form of an ensemble of flux tubes or as a magnetic layer of 'diffuse field' from which the flux tubes thread out by some sort of MHD instability is still an open question.

In any case, the field is already in the form of intense flux tubes when it enters the convection zone and buoyantly rises through it to emerge as sunspots at the solar surface. A stability analysis yields values of the order of 10^5 G prior to eruption. There are independent arguments in favor of the intense (super-equipartition) fields. One is that a flux tube of equipartition strength at the bottom of the convection zone would become extremely weak when rising across several scale-heights through the turbulent convection zone, contrary to the coherent and concentrated form of bipolar active regions

observed at the solar surface. Another is that the results of the numerical simulations are in agreement with the observed basic properties of active regions only for field strengths of the order of 10^5 G.

Although the production of the strong toroidal field is localized at the lower boundary of the convection zone, the exact process of intensification is not quite understood. It is possible that the explosion process or the formation of Ω-loops operate in conjunction with differential rotation (Moreno-Insertis *et al* 1995). In any case, the existence of super-equipartition fields requires a modified dynamo approach. A possible scenario is the one depicted above: a dynamo based on the instability of strong magnetic flux tubes. Alternatively, one could imagine a dynamo with spatial separation of the generation processes for the poloidal and toroidal components.

A complete theory encompassing in a self-consistent way the generation, structure, dynamics and evolution of magnetic fields in stellar convection zones does not exist; this lack of self-consistency is basically due to our insufficient comprehension of turbulent flows.

Solar Interior: Emerging Magnetic Flux Tubes

The magnetic field observed in the photosphere and at higher levels of the solar atmosphere is generated in the convective envelope that extends along the first 200 000 km below the solar surface (see DYNAMOS: SOLAR AND STELLAR and SOLAR INTERIOR). To properly understand the solar magnetic cycle, it is necessary to explain the processes whereby the magnetic field, once generated, emerges across the convection zone and then appears at the surface. In fact, when we observe the birth at the solar surface of sunspots and, more generally, active regions, which are structures with an intense magnetic field, we are witnessing the final stages of the emergence of magnetic flux from the solar interior. Looking at the solar disk face-on, what we see after some hours of eruption of magnetic flux is a simple bipolar structure consisting of two patches of mutually opposite magnetic polarity, each containing one or more sunspots (see SOLAR ACTIVE REGIONS and SOLAR ACTIVITY COMPLEXES). The imaginary line linking the two patches is generally oriented in an approximate east–west direction. After the first stages of formation, the two patches separate from each other, reaching a mutual distance of up to 150 000 km. This pattern of behavior seems to be followed by most incipient active regions in the Sun. A simple interpretation of this process is that, when an active region is formed, we are witnessing the emergence at the surface of a large magnetic tube (or, rather, a bunch of them) oriented in a direction roughly parallel to the equator (figure 1). The *roots* of this magnetic tube are located at some deep level below the surface. By studying the dynamics of magnetic tubes in the convection zone including, in particular, why and how they rise and appear at the surface and comparing the conclusions with the actual observations of the birth of active regions, we can therefore gain precious insights into the structure and dynamics of the solar interior.

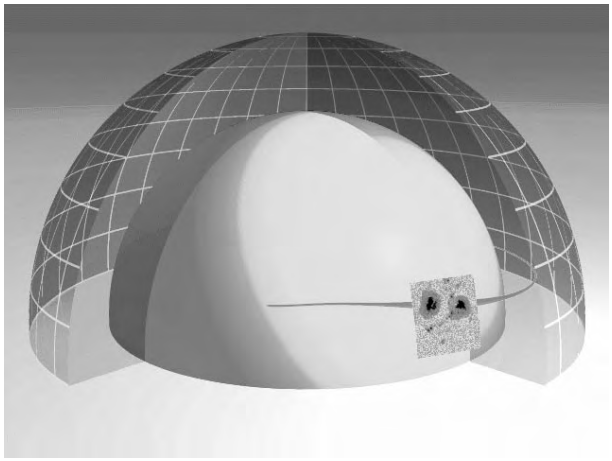

Figure 1. Illustration of a magnetic tube rooted in the deep solar interior whose apex has emerged through the convection zone producing an active region at the surface. The transparent spherical surface with a grid represents the solar surface and the inner solid sphere corresponds to the solar interior below the convection zone. (Figure courtesy of P Caligari.)

The magnetic field in the deep convection zone and the instabilities that trigger its eruption

According to current understanding, the magnetic field that we see in active regions is originated and stored in a magnetized sheet at the bottom of the convective envelope, possibly with the shape of a spherical shell or a spherical band extending on both sides of the equator roughly coinciding with the region known as the *overshoot layer* right beneath the convection zone. A simple possibility (favored by many theoreticians, who are looking for simplicity wherever possible) is that the magnetic field, instead of permeating the whole sheet, adopts the form of a collection of magnetic rings or *hoops* around the Sun, the axes of which roughly coincide with the solar rotation axis; in between the rings the plasma has a much weaker magnetic field. Another possibility, on the opposite extreme, is that the field is continuous and fills up a large fraction of the sheet instead of being concentrated into tubes or rings. In either case, the magnetic field in the sheet does not stay put forever: at some point, it becomes unstable through a process of a kind collectively known as *buoyant instabilities*. The basic idea is that, under a variety of physical conditions, a portion of matter in the solar interior or atmosphere, if given an initial kick upward, will not stop rising because it becomes increasingly light with respect to its surroundings (and thus, also increasingly buoyant).

In the presence of an ordered magnetic field, a classical example of buoyant instability is the *Parker instability*. To understand how it operates, imagine a magnetic tube lying horizontally in the deep convection zone (and, for a graphical image, compare it with a bunch of flexible plastic tubes filled with gas lying at the bottom of a gas tank). If a certain stretch of the magnetic tube is moved upward, then, under given conditions for the temperature distribution in the region, the matter within the tube moves in such a way that the apex of the deformed stretch becomes increasingly light with respect to its surroundings. In this way, the initial upward movement becomes amplified and does not stop. The conditions under which this unstable process takes place are fulfilled for isolated magnetic tubes in the deep solar convection zone if their field strength is above a threshold of roughly 100 000 G (some 300 000 times the strength of the Earth's surface magnetic field). The field strength may indeed be this high at the bottom of the solar convection zone; the Parker instability is thus one of the fundamental mechanisms that can explain why the magnetic field leaves the deep solar interior and erupts at the solar surface. In the alternative view, with the magnetic field permeating a whole sheet instead of being in the form of individual tubes, there is also a mechanism for triggering the eruption of magnetic flux, called the magnetic Rayleigh–Taylor

instability. This instability (akin to the instability that ensues when heavier fluid rests on a less dense one) may lead to the disruption of the magnetic structure and the formation of rising buoyant magnetic tubes.

Modeling the inner workings of the Sun in a computer

As a result of the buoyant movement of the magnetic tubes, magnetic flux is brought all the way from the bottom of the convection zone to the surface, where we see it appearing as sunspots and other magnetic elements. If we could contemplate the solar interior, then we would see how the magnetic tube stretches from the bottom of the convection zone, where it is rooted, all the way to the surface and into the solar atmosphere. Sunspots are, in this sense, just a *cut* across the flanks of an erupted magnetic tube.

In the past two decades there has been a true *revolution* in our understanding of the detailed physics of the process of rise of the magnetized plasma, thanks, among other things, to the possibility of detailed numerical simulation using the impressive increase in computing power and the development of simplified models. A first generation of models (the so-called *slender flux tube models*) use the fact that the radius of the magnetic tube progenitors of active regions (possibly some 1000 km only) is very small with respect to the size of the solar structures at the bottom of the convection zone. The slender flux tube models use a drastically simplifying approach; given that the tubes are thin, one can, in a first go at the problem, neglect the complicated transverse structure of the tubes in each cross section. There results a self-consistent set of equations, the *thin flux tube equations*, which contain the most essential ingredients to describe why the tubes rise and what the main features of the resulting structure are. The solution of those equations yields a simple model for the process of emergence of flux.

One such model can be seen in figures 2 and 3. The plasma in the rising loop of the tube experiences a huge expansion as it adapts to the new environments it crosses in its upward journey: the pressure of the solar plasma is a billion times higher at the bottom of the convection zone than at its topmost levels. This causes a marked weakening of the field intensity along the rise. On the other hand, as a result of the unstable evolution, the lower reaches of the tube descend to somewhat deeper levels and become anchored in the overshoot region right beneath the convection zone. The matter in the *overshoot region* is being stirred because of the intrusion of convection cells from the overlying layers, but, in itself, is stable to convection. A magnetic tube in sufficiently low levels in that region is stable to the buoyant instabilities and remains there while the rising sections of the tube are on their way to the surface.

The thin tube models have provided explanations for some of the observed large-scale features of active regions. One of them concerns an old observational result: Hale, Ellerman, Nicholson and Joy observed in 1919 that the *main axis* of an active region (i.e. the imaginary line linking the centers of the two patches of opposite polarity) and the solar equator were not strictly parallel but, rather, subtended an angle of, typically, several degrees with opposite sign in the northern and southern hemisphere. The magnitude of this angle was larger the higher the latitude at which the active region appeared. The thin tube models explain the origin of this empirical law as a consequence of the rotation of the Sun or, more precisely, through the action of the Coriolis force. This can be understood by comparing this phenomenon with the formation of an anticyclone in the Earth's atmosphere when air moves away from a high-pressure area (which is also a consequence of the Coriolis force). Studying the motion of the individual mass elements of the tube along the rise, one can see that those along the flanks move sideways away from the mass element at the apex. The Coriolis force thus brings about a rotation of the vertical plane containing the magnetic tube. When the tube reaches the surface, this is seen as a *tilt* of the main axis of the active region (clearly visible in figures 1 and 2).

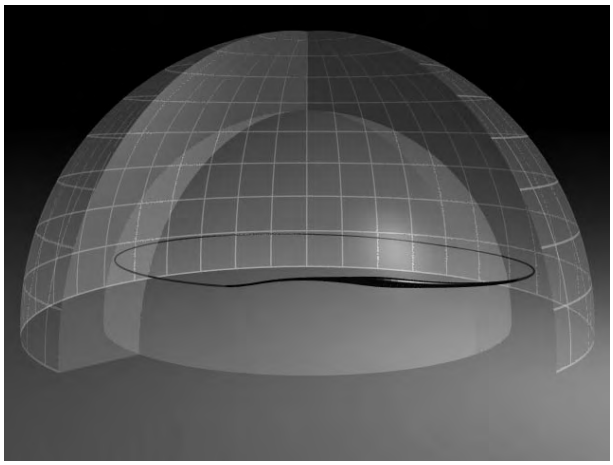

Figure 2. Result of a time-dependent calculation of emergence of magnetic flux from the bottom of the convection zone. The equations that govern the time evolution of a thin magnetic tube have been solved starting with a Parker-unstable configuration.

A further empirical law (in this case, a much more recent one) concerning active regions is the fact that the mutual separation of two patches of opposite polarity does not proceed in a symmetrical way: it appears that one side (the one closest to the western limb of the Sun) moves away from the line separating the opposite polarities much faster than the other side. This phenomenon can also be explained by the thin tube models and is, again, a consequence of the solar rotation: because of the conservation of angular momentum, the two flanks of the rising loop become differently inclined with respect to the vertical direction (figure 3). When the tube breaks out at the photosphere, this difference in inclination translates into a higher speed of separation of one of the branches of the rising loop from the apex than the other branch.

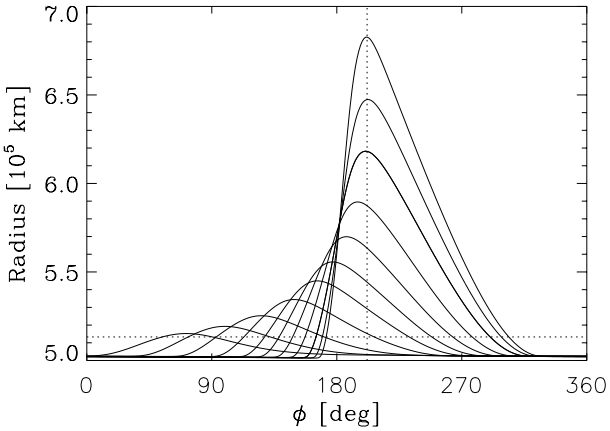

Figure 3. Several stages of the evolution of a rising magnetic tube with the horizontal axis representing solar longitude and the vertical axis height (measured by the radial distance to the solar center). Note the asymmetry in inclination of the flanks of the tube.

Perhaps the most interesting result of the thin flux tube models is an estimate of the strength of the magnetic field at the bottom of the convection zone. For the thin tube models to yield a good agreement with the empirical observations of active regions discussed above, the field intensity in the bottom layers must be of the order of 100 000 G. This result came as a surprise when it was first clearly stated since most people thought it to be much weaker, some 1000 to 10 000 G. That the field must be as strong as 100 000 G can be understood in different ways: first, if the tubes in the deep convection zone had weaker fields, then, upon the huge expansion taking place along the rise, they would yield very weakly magnetized regions rather than concentrated tubes. Second, the risetime of magnetic tubes with weaker field strength is much longer, so that the Coriolis force has a much larger impact on the rising tube. Consequently, the resulting active regions would have features not seen in the actual Sun like: (a) the eruption at the surface would take place at high solar latitudes, (b) their main axes would systematically subtend a large angle to the equator and (c) the asymmetric motion of the polarities discussed in the previous paragraph would be extreme.

Recent research: twists, buckles, inner structure and aerodynamic properties of a rising magnetic tube

In recent years, the research on the emergence of magnetic flux has focused on issues concerning the transverse structure and the three-dimensional stability of the rising magnetized regions. One of the issues deals with the question of whether a magnetic tube that is rising across the convection zone can maintain its unity, i.e. if it can rise without splitting into smaller strands. To understand the problem, we can recall the case of rising columns of hot air in the Earth's atmosphere, typically occurring on sunny summer days on a plain: the rising column of air typically turns into two horizontal rolls (also called vortex tubes) which rotate in opposite directions. Similarly, a buoyantly rising magnetic tube can easily split into two horizontal vortex tubes. Vortex tubes suffer aerodynamic lift forces, so that their path may deviate significantly from the simple path calculated with the standard thin flux tube model. A branch of research has therefore been devoted to studying the details of the internal structure of the tube and of the surrounding boundary layer. This includes the generation of vorticity, especially around the tube boundary, the formation of a trailing wake, the aerodynamic lift and drag experienced by the tube, etc. A major result of these studies is that the magnetic field lines must be *twisted* for the tube to preserve its unity during the rise, i.e. they must be wound around the tube's main axis instead of running more or less parallel to it. The magnetic field thus has both a component parallel to the tube's axis *and* a component contained within the cross section of the tube. It is the Lorentz force associated with the latter that gives the tube the possibility to withstand the forces that tend to break it into vortex rolls.

Another related issue subject to scrutiny in recent years is the development of kink instabilities (well known from the plasma fusion research in laboratories) in magnetic tubes with twisted field lines in the solar interior. The instability has to do with the fact that the magnetic field exerts a tension along its lines. As a consequence, if the tube is sufficiently twisted it may *buckle* and produce *kinks*, like a simple rope subject to tension and twist. This is being studied with the help of computer simulations. An interesting result of this research is a possible explanation for the peculiar behavior of a special class of active regions, the so-called *δ-spots*. *δ*-spots are exceptional active regions with the two patches of opposite polarity close together and with the main axis of the region inclined at high angles with respect to the solar equator. These peculiar features may be explained as the arrival at the surface of a strongly twisted magnetic tube in an advanced stage of development of the kink instability. An easy pictorial image for this is a highly twisted rope which is quickly developing buckles: the direction of the rope in the buckles may deviate considerably from the original direction of the unkinked rope.

In parallel to the research into the behavior of individual magnetic tubes, there have been several studies of the physics of continuous magnetic field distributions. The buoyant instabilities in the latter are in several ways similar to the magnetic tube counterparts. However, the techniques for studying them are different. For instance, there is no equivalent to the thin tube approximation, so that there are to date no full simulations of the eruption of a continuous magnetic layer in the lower convection zone all the way until the up-going elements reach the solar surface. However, these studies have provided interesting insights into how magnetic flux tubes may form out of a continuum of field, the subsequent three-dimensional instabilities, etc.

All of the foregoing studies require the use of the largest and most advanced computers available: if the pace of increase in computing power continues at the current rate, we can expect substantial advances in our understanding of the physics of the magnetic field in the solar interior and its emergence to the surface.

Solar Interior: Energy Generation

Energy generated deep in the SOLAR INTERIOR via the nuclear fusion of hydrogen into helium provides the 3.9×10^{26} J s^{-1} radiated by the surface of the Sun. Beginning in the 1920s the foundations of nuclear astrophysics were laid on the basis of (a) the recognition that the solar system was several billion years old (based on the decay of radioactive elements such as uranium), (b) the recognition that, in contrast with inadequate chemical and gravitational energy sources, the then newly discovered nuclear reactions could readily supply the energy required to account for the luminosity of the Sun over this lifetime and (c) the recognition by Gamow in the late 1920s of the role of quantum mechanical tunneling in making it possible for these reactions to occur in the solar interior where kT was most probably equivalent to only a few keV, well below the repulsive Coulomb barrier. Building on that foundation, in the late 1930s, Weizsäcker and Bethe independently laid out the energetics and many of the theoretical details for converting hydrogen to helium in the solar interior via the pp chain and the CN cycle.

At the temperatures and densities characteristic of the solar interior ($T \approx 16 \times 10^6$ K and $\rho \approx 150$ g cm^{-3}), interacting nuclei reach a Maxwellian equilibrium distribution in a time that is infinitesimal compared with the mean lifetime of these nuclear reactions and decays. Therefore it is possible to determine the thermally averaged nuclear reaction rate by folding its energy-dependent cross section $\sigma(E)$ with the Maxwell–Boltzmann distribution as

$$R_{12} = \frac{n_1 n_2}{1+\delta_{12}} \langle \sigma \nu \rangle_{12}$$

where

$$\langle \sigma \nu \rangle_{12} = \left(\frac{8}{\pi \mu (kT)^3} \right)^{1/2} f_0 \int_0^\infty E \sigma(E) \exp(-E/kT)\, \mathrm{d}E$$

and where f_0 is a correction to the laboratory (bare-nucleus) cross section measurements to take into account the effects of plasma screening in STELLAR INTERIORS. (This correction is the order of 1.20–1.25 for pp-chain reactions in the solar interior.) As noted above, in the solar interior nuclear reactions take place via tunneling at energies which are far below the Coulomb barrier. One of the major sources of the energy dependence of the cross sections arises from this tunneling whose principal effects can be factored out by reexpressing the cross section in terms of the astrophysical S factor,

$$S(E) = \sigma(E) E / \exp(2\pi\eta)$$

where $\exp(-2\pi\eta)$ is the usual quantum mechanical penetration term associated with tunneling under the Coulomb barrier, in which $\eta = Z_1 Z_2 e^2/\hbar\nu$, so that

$$\langle \sigma \nu \rangle_{12} = \left(\frac{8}{\pi \mu (kT)^3} \right)^{1/2} f_0 \int_0^\infty S(E) \exp(-2\pi\eta) \times \exp(-E/kT)\, \mathrm{d}E. \quad (1)$$

An example of the comparison between the energy dependences of $\sigma(E)$ and $S(E)$ is shown in figure 1, for the case of the ^{3}He(^{3}He,2p)^{4}He reaction; in the energy range plotted in this figure, 20 keV$\leq E_{\mathrm{cm}} \leq$ 350 keV, $\sigma(E)$ varies by nearly a factor of 10^{10} while $S(E)$ varies by only about 20%. For reactions in which there are no important low-energy resonances so that $S(E)$ is only a slowly varying function of energy (which is the case for all the pp-chain reactions), the dominant energy dependence in the integrand in equation (1) is then given by the product of barrier-penetration and Maxwell–Boltzmann terms, shown schematically in figure 2. The centroid E_0 of the peak of the integrand (the 'Gamow peak') and ΔE_0 (its width at 1/e of its maximum value) are given by

$$E_0 = [\pi (Z_1 Z_2 e^2/hc) kT (\mu c^2/2)^{1/2}]^{2/3}$$
$$\text{and } \Delta E_0 = 4(E_0 kT/3)^{1/2}.$$

Because of the effects of the Coulomb barrier, laboratory measurements of the cross sections for these reactions can typically be carried out only at energies well above E_0. Because of its much smaller energy dependence, the $S(E)$ function is then frequently a convenient way to extrapolate these measurements to the lower energies of interest in the $\langle \sigma \nu \rangle_{12}$ integral in equation (1). It is usually convenient to characterize the energy dependence of $S(E)$ in terms of its intercept and derivatives at $E = 0$: $S(0)$, $S'(0)$ and $S''(0)$.

$$S(E) = S(0) \left(1 + \frac{S'(0)}{S(0)} E + \frac{1}{2} \frac{S''(0)}{S(0)} E^2 \right). \quad (2)$$

For a more detailed discussion of these rate equations, the reader should consult one of the standard reviews listed in the bibliography at the end of this article.

The proton–proton chain

The pp chain (figure 3) is responsible for ≈98% of the $4\,^1\mathrm{H} \rightarrow {}^4\mathrm{He} + 2e^+ + 2\nu_e$ nuclear-fusion energy generation in the Sun. The critical reactions in the chain are (i) the $^1\mathrm{H} + {}^1\mathrm{H} \rightarrow {}^2\mathrm{D} + e^+ + \nu_e$ reaction which is the slowest link in the pp chain and whose rate therefore determines the central temperature of the Sun, (ii) the ^{3}He(^{3}He,2p)^{4}He and ^{3}He(α, γ)^{7}Be reactions whose relative rates determine the fraction of pp-chain terminations which produce neutrinos with energies greater than the $E_{\nu\,\mathrm{max}} = 420$ keV from the pp reaction and (iii) the ^{7}Be(e^-, ν_ε)^{7}Li and ^{7}Be(p,γ)^{8}B reactions whose relative rates determine the fraction of terminations which result in the production of high-energy neutrinos, $E_{\nu\,\mathrm{max}} \approx 14$ MeV. The three terminations for the pp chain (as well as the various permutations of the CN cycle) all generate the same total energy (25.731 MeV, which is simply the mass difference between $4\,^1$H and ^{4}He). However, the amount of that energy lost directly from the center of the Sun via the two neutrinos can be quite different, varying from 0.420 MeV for the ^{3}He(^{3}He,2p) termination to ∼7 MeV for the ^{7}Be(p,γ) termination. (For a more complete discussion see SOLAR INTERIOR: NEUTRINOS.)

The ^1H+$^1H\rightarrow$ ^2D+e^+ + ν_e reaction

The ^{1}H +^{1} H $\rightarrow$ ^{2}D + e$^+$ + ν_e reaction takes place via the weak interaction and is by far the slowest link in the pp chain; its $S_{11}(0)$ intercept is roughly 10^{20} times smaller than the intercepts for the other reactions in the chain. Its cross section is not currently measurable in laboratory experiments and must instead be determined on the basis of measurements of the properties of the weak interaction—for example, measurements of the beta decay of the neutron and of superallowed $0^+ \rightarrow 0^+$ beta decays. On this basis, the astrophysical S factor for this reaction can be written as

$$S_{11}(E) = 6\pi^2 m_p c\alpha \ln 2 \frac{\Lambda^2}{\gamma^3}\left(\frac{G_A}{G_V}\right)^2 \frac{f_{pp}^R}{(ft)_{0^+\rightarrow 0^+}}(1+\delta)^2$$

where Λ is the overlap integral between the pp and deuteron wavefunctions, γ is the deuteron binding wavenumber, G_A and G_V are the usual axial-vector and vector weak coupling constants, f_{pp}^R is the phase space factor for the pp reaction, $(ft)_{0^+\rightarrow 0^+}$ is the ft value for superallowed $0^+ \rightarrow 0^+$ beta decay and δ is the fractional correction to the nuclear matrix element due to exchanges of π and ρ mesons. Utilizing the current best values for these parameters yields the following values for the $S_{11}(0)$ intercept and its energy derivative, $S'_{11}(0)$:

$$S_{11}(0) = 4.00\times10^{-22}\,\text{keV b} \qquad \text{and} \qquad S'_{11}(0) = 4.5\times10^{-24}\,\text{b}.$$

Currently the largest source of uncertainty in this reaction rate is in the parameter δ.

The ^{3}He(^{3}He,2p)^{4}He reaction

Since ^{4}Li is particle unstable, one important aspect of the ^{3}He(^{3}He,2p)^{4}He reaction is the fact that it provides a termination for the pp chain without requiring the presence of previously synthesized ^{4}He. Recently, the LUNA facility (Laboratory for Underground Nuclear Astrophysics) has been used to carry out measurements of the ^{3}He(^{3}He,2p)^{4}He reaction down to the region of the Gamow peak. (The LUNA Collaboration includes scientists from Italy, Germany and the US.) Using the

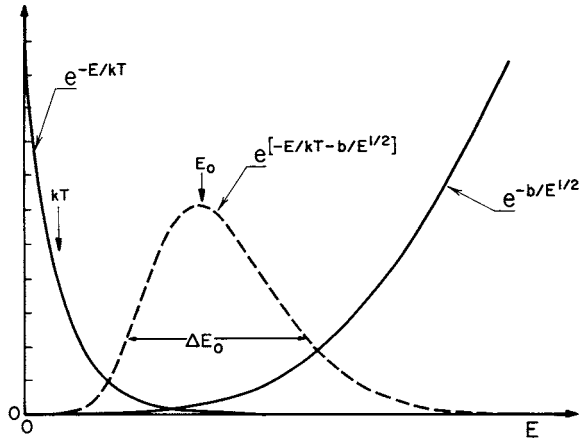

Figure 2. Energy dependence of the integrand in equation (1).

Gran Sasso tunnel in the the Appennine Mountains in central Italy, as a cosmic ray shield, it has been possible to measure cross sections as small as 0.76 pb and to thereby carry out direct measurements of this reaction down to $E_{\rm cm} = 20.8$ keV. Together with earlier above-ground measurements of the Bochum group, these measurements cover more that half of the actual Gamow peak for this reaction, $E_0 \approx 22$ keV at the center of the Sun.

In measurements made for $E_{\rm cm} \geq 100$ keV the distance of closest approach for these nuclei is inside the electron cloud so that their interaction is as essentially bare nuclei. In contrast, at the low energies used in the LUNA measurements described above, the interacting nuclei have a distance of closest approach that is near or outside the atomic radius $R_{\rm a}$, so that electron screening corrections are necessary in order to relate these laboratory measurements $\sigma_{\rm sc}$ to the cross sections that would be measured for bare nuclei $\sigma_{\rm b}$. This screening correction is given by

$$\sigma_{\rm b} = \sigma_{\rm sc} \exp(-\pi\eta U_{\rm e}/E_{\rm cm}) \qquad \text{where } U_{\rm e} = Z_1 Z_2 e^2/R_{\rm a} \tag{3}$$

and where η is the usual Coulomb parameter. For the ^{3}He(^{3}He,2p)^{4}He reaction ($U_{\rm e} = 240$ eV), at $E_{\rm cm} = 22$ keV this corresponds to a 20% correction, while at $E_{\rm cm} > 150$ keV the correction is $\leq$1%. Note that this correction should not be confused with the plasma screening correction which must be used to relate laboratory measurements of bare-nuclear cross sections to reaction rates in plasmas.

A fit (see figure 4) to the LUNA and Bochum data sets (which are consistent with each other and with earlier higher-energy measurements), including the screening correction of equation (3), determines the following bare-nucleus values for the $S_{33}(0)$ intercept and for $S_{33}(E_0)$ at the center of the Gamow peak:

$$S_{33}(0) = 5.4 \pm 0.4 \text{ MeV b}$$
$$\text{and} \qquad S_{33}(E_0) = 5.3 \pm 0.4 \text{ MeV b}.$$

The ^{3}He(α, γ)^{7}Be reaction

The relative rates of the ^{3}He(^{3}He,2p)^{4}He and ^{3}He(α, γ)^{7}Be reactions determine the fraction of pp-chain terminations which produce neutrinos with energies greater than the $E_{\nu\,\rm max} = 420$ keV available from the pp reaction. While there have been nine independent sets of measurements of the cross section for the ^{3}He(α, γ)^{7}Be reaction, because the cross section for this reaction is approximately 10 000 times smaller than the cross section for the ^{3}He(^{3}He,2p)^{4}He reaction none of these measurements has been carried out close to the Gamow peak for this reaction. Therefore, the rate of this reaction in the solar interior must be determined from an extrapolation of the higher-energy measurements. Extrapolation is always dangerous, but fortunately the energy dependence of this reaction is well described by a variety of nuclear models (ranging from ^{3}He$\otimes^4$He cluster models to microscopic potential models) which agree within a per cent or two and which can then be used to carry out the extrapolation with confidence. The good agreement between these calculations arises from the fact that over the energy range 0 keV$\leq E_{\rm cm} \leq$ 2500 keV this reaction is a non-resonant direct-capture process for which almost all the contributions to the matrix element come from the region outside the nuclear potential well. Figure 5 displays the agreement between such calculations and the measured data sets from the four experiments which cover significant energy ranges; for one of the experiments the data extend up to $E_{\rm cm} = 2500$ keV (still well below the first unbound ^{7}Be state at $E_{\rm cm} = 2983$ keV) with the same quality of agreement between the model calculations and the measurements.

A weighted mean of the extrapolation of the nine independent experiments determines the intercept $S_{34}(0)$, while the theoretical calculations determine the slope $S'_{34}(0)$:

$$S_{34}(0) = 0.53 \pm 0.05 \text{ keV b}$$
$$\text{and} \qquad S'_{34}(0) = -3.0 \times 10^{-4} \text{ b}.$$

In spite of the fact that $S_{34}(0)$ is $\approx 10^4$ times smaller than the corresponding $S_{33}(0)$, the ^{3}He(α, γ)^{7}Be reaction can compete with the ^{3}He(^{3}He,2p)^{4}He reaction in the solar interior because of the large abundance of ^{4}He in the solar interior relative to ^{3}He; ^{4}He/^{3}He$\sim 10^3$–10^5, depending on the location. Integrated over the solar interior, solar model calculations find that 16% of the pp-chain terminations occur via the ^{3}He(α, γ)^{7}Be reaction while the remaining 84% occur via the ^{3}He(^{3}He,2p)^{4}He reaction.

The ^{7}Be(e^-,ν_e)^{7}Li decay

For the 16% of the pp-chain terminations that proceed through the ^{3}He(α, γ)^{7}Be reaction, the branch between ^{7}Be electron capture and ^{7}Be proton capture determines the fraction of terminations which produce high-energy neutrinos ($E_{\nu\,\rm max} \approx 14$ MeV) via the beta-decay ^{8}B. In this way, the relative rates of the ^{7}Be(e^-, γ_e)^{7}Li decay and the ^{7}Be(p,γ)^{8}B reaction are critical in determining both

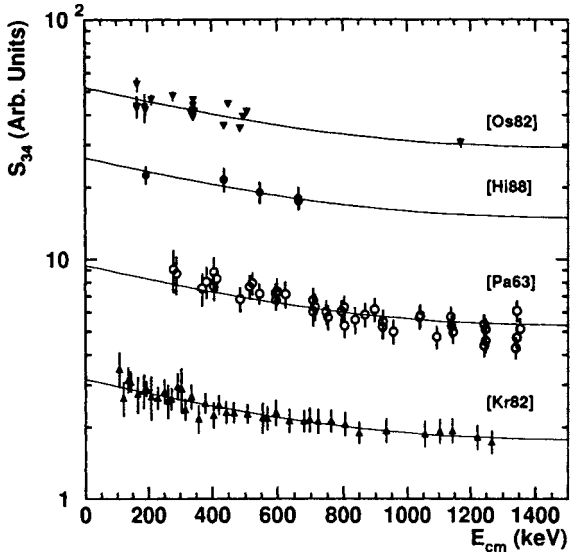

Figure 5. Comparison of the energy dependence of a theoretical calculation of $S(E)$ with the measured data sets from four independent ^{3}He(α, γ)^{7}Be experiments.

the effective energy generation of the pp chain and the resulting neutrino energy spectrum.

The decay of ^{7}Be via the capture of its own atomic electrons has been well studied in the laboratory; it has a measured half-life of 53.29 ± 0.07 days, with a branching ratio of 89.5% for decays to the ground state of ^{7}Li ($E_\nu = 0.862$ MeV) and 10.5% to the first exited state of ^{7}Li ($E_\nu = 0.384$ MeV). However, in the solar interior ^{7}Be atoms will be mostly ionized, so that any ^{7}Be(e^-, ν_e)^{7}Li decays will occur mostly via the capture of continuum electrons from the plasma, and the resulting decay rate will be proportional to the electron density in the plasma. Calculations of the continuum decay rate combined with calculations of the bound-state electron populations and their contributions to the decay rate determine

$$1/\tau\ (\mathrm{s}^{-1}) = (1/\tau)_\mathrm{c} + (1/\tau)_\mathrm{b} = 5.60 \times 10^{-9}\,\frac{\rho(1+X_\mathrm{H})}{2}\,T_6^{-1/2}[1 + 0.004(T_6 - 16)].$$

Integrated over the solar interior, this corresponds to 82% of the decays coming from the capture of continuum electrons from the plasma and 18% from bound atomic electrons. Under conditions typical of the hydrogen burning region in the solar interior ($\rho = 100$ g cm^{-3}, $X_\mathrm{H} = 0.50$, $T_6 = 13.8$), this corresponds to a ^{7}Be half-life of 70 days (compared with the laboratory value of 53 days).

The ^{7}Be(p,γ)^{8}B reaction

The fraction of pp-chain terminations proceeding through the ^{7}Be(p,γ)^{8}B reaction is especially significant (i) because of the production of high-energy (^{8}B) neutrinos which are crucial for a number of solar neutrino detectors (see NEUTRINO ASTRONOMY) and (ii) because of the ≈27% energy loss associated with the escape of those neutrinos from the center of the Sun. The rate of the ^{7}Be(p,γ)^{8}B reaction is therefore particularly important for probing and understanding energy generation in the solar interior. In spite of the significant added complications associated with the radioactive nature of ^{7}Be, seven such experiments have been carried out using ^{7}Be targets to measure the rate of this reaction. This is another case in which the $S_{17}(0)$ intercept must be determined by extrapolation from

Copyright © Nature Publishing Group 2001

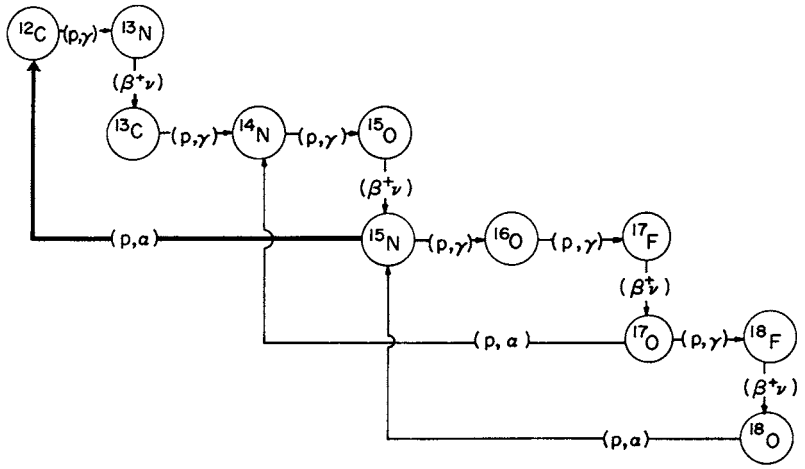

Figure 6. The CNO tri-cycle.

values measured at energies well above the Gamow peak. In this case the low-energy cross section is again non-resonant, and there are a number of consistent theoretical calculations which provide a basis for the extrapolation. The full range of the $S_{17}(0)$ results from these experiments covers a variation of a factor of $\approx$2 between the highest and lowest values. Following a critical review of all of these experiments, the 1997 INT Workshop on Solar Fusion Cross Sections recommended the adoption of

$$S_{17}(0) = 19^{+4}_{-2}\ \text{eV b}. \qquad (4)$$

A quadratic fit to the theoretical energy dependence over the range 0 keV $\leq E_{\rm cm} \leq$ 300 keV, using the form of equation (2), determines

$$\frac{S'(0)}{S(0)} = -0.7\ \text{MeV}^{-1} \qquad \text{and} \qquad \frac{S''(0)}{S(0)} = +3.8\ \text{MeV}^{-2}.$$

These results, integrated over the solar interior, determine that the ^{7}Be(p,γ)^{8}B termination accounts for only 0.02% of the pp-chain terminations. While this is clearly not an important consideration as far as solar energy generation is concerned, because of its high-energy neutrinos this branch is still the most important termination for a number of solar neutrino experiments. The interpretation of the results of those experiments therefore requires that $S_{17}(0)$ be more accurately measured.

We appear to be on the threshold of a series of promising new experiments to measure the rate of this reaction, using a variety of new techniques, such as ^{7}Be beams, new ^{7}Be–target strategies and the Coulomb dissociation of ^{8}B. These new techniques will have the advantages of avoiding some of the systematic uncertainties associated with the previous experiments, but at the same time these new techniques will have systematic uncertainties of their own which will need to be understood in order to interpret the results of such experiments together with the previous (p,γ) experiments. Initial measurements utilizing a ^{7}Be beam have recently been reported by the NABONA collaboration, and initial Coulomb dissociation measurements have provided preliminary results which are not inconsistent with equation (4) and are encouraging for further studies to provide an independent determination of $S_{17}(0)$.

The carbon–nitrogen cycle

The CN cycle uses ^{12}C as a nuclear catalyst in the conversion of $4\,^1\text{H} \rightarrow {}^4\text{He} + 2e^+ + 2\nu_e$. Because of the roles of various branch points available in the CN cycle, the whole process (see figure 6) is now described as a 'tri-cycle'. Because of the high Coulomb barriers of the nuclear reactions involved in the CNO cycles (compared with those in the pp chain) and the relatively low temperature in the solar core (compared with more massive stars), the CNO tri-cycle is responsible for only a small fraction ($\leq$2%) of the energy generated in the Sun. Based on a comparison of the measured cross sections for the ^{15}N(p,γ)^{16}O and ^{15}N(p,α)^{12}C reactions, the main cycle, terminating via the ^{15}N(p,α)^{12}C reaction, is responsible for $\geq$99.5% of this small fraction.

By far the slowest reaction in the CN cycle is the ^{14}N(p,γ)^{15}O reaction—typically more than 100$\times$ slower than the other reactions for temperatures between 15×10^6 and 20×10^6 K. It is the rate of this reaction which then determines the rate of the CN cycle. Recent, extensive measurements of the ^{14}N(p,γ)^{15}O reaction show evidence for important interference effects involving the high-energy tail of a subthreshold resonance ($E_{\rm cm} = -504$ keV; $J^\pi = 3/2^+$). However, the magnitude of these interference effects at low energies is not well determined by these recent data. A combination of these data (0.20 MeV $\leq E_{\rm cm} \leq$ 3.6 MeV) and earlier, lower-energy data (0.100 MeV $\leq E_{\rm cm} \leq$ 0.135 MeV) has been used by the 1997 INT Workshop on Solar Fusion Cross Sections to determine a current 'best' value of $S(0)$ for this reaction,

$$S_{^{14}\text{N(p,}\gamma\text{)}}(0) = 3.5^{+0.4}_{-1.6}\ \text{keV b}.$$

Dirac House, Temple Back, Bristol, BS1 6BE, UK

New experiments are clearly needed in order to better determine the cross section of this reaction and, thereby, the rate of the CN cycle.

Summary

Energy generation in the solar interior represents an intertwining of the effects of the gravitational and nuclear forces. The total gravitational potential energy available from the collapse of the proto-solar nebula to the size of the Sun would be only sufficient to generate the solar luminosity for the order of 50 million years (≈1% of the current age of the Sun). However, the contraction of the proto-solar nebula converted gravitational potential energy to thermal kinetic energy which heated the solar interior until the $4\,^1\mathrm{H} \rightarrow {}^4\mathrm{He}$ nuclear fusion reactions became fast enough to generate the solar luminosity; at that point an equilibrium was established between the nuclear fusion energy supporting the star and the attractive gravitational force containing this fusion device.

Based on the measurements and extrapolations of nuclear cross sections discussed above and their integration over the solar interior in a standard solar model (see SOLAR INTERIOR: STANDARD MODELS), we find the following percentages for each of the significant $4\,^1\mathrm{H} \rightarrow {}^4\mathrm{He}$ processes:

pp chain	98.2%
^{3}He(^{3}He,2p) termination	82.5%
^{7}Be(e^-,ν_e) termination	15.7%
^{7}Be(p,γ) termination	0.02%
CN cycle	1.8%

Solar Interior: Equation of State and Opacity

In stellar models, the equation of state and opacity are, together with nuclear reaction rates, the fundamental material properties. The structure of a star is a result of (i) a balance of forces, (ii) a balance between the energy loss at the stellar surface and energy generation in the core and (iii) stationary energy transport between the core and the surface (see SOLAR INTERIOR: STANDARD MODELS). The balance of forces, described as hydrostatic equilibrium, results in a relation between the pressure gradient and the gravitational acceleration. The force of gravity is determined by the density distribution in the star: thus stellar modeling requires a relation between density and pressure through the specific properties of the matter. More precisely, the relevant properties of stellar matter are expressed by the *equation of state*, connecting pressure p, density ρ, temperature T and composition. A simple example is the perfect gas law for a fully ionized gas, which may be written as $p = \mathcal{R}\rho T/\mu$; here $\mathcal{R}$ is the gas constant and μ is the mean molecular weight of the various species contained in the gas. Clearly μ depends on the composition, which is often characterized by the fractional mass abundances X, Y and Z of hydrogen, helium and heavier elements.

The temperature of the stellar interior is determined by the energy balance. In much of the Sun, energy transport takes place through radiation and depends on absorption coefficients, obtained from atomic physics, which determine the *opacity* of stellar matter. It was also realized early on that the requirements of radiative transport could result in a temperature gradient so steep that a star would become convectively unstable: convection, where hot elements of gas rise and then generally dominate the energy transport. In the Sun this occurs in about the outer 30% of the radius. Because of the efficiency of convective energy transport, it generally requires a temperature gradient only slightly in excess of the adiabatic gradient, a thermodynamic quantity derived from the equation of state. Another consequence of the equation of state, adiabatic sound speed, plays a crucial role in helioseismology (see SOLAR INTERIOR: LOCAL HELIOSEISMOLOGY; HELIOSEISMOLOGY: THEORY).

The equation of state appears as a necessary part of stellar modeling as well as of any opacity calculation. For the latter, it has to provide ionization equilibrium concentrations and level populations. However, the interest in the stellar equation of state is not merely motivated by astrophysics. It has turned out that one star—the Sun—is very special in two respects. First, the methods of helioseismology allow us to infer conditions in the solar interior very accurately (in particular sound, speed and density). Second, in the solar convection zone, helioseismology presents an opportunity to isolate the question of the equation of state from opacity and nuclear reaction rates, since the stratification is essentially adiabatic and thus determined by thermodynamics. Thus, the Sun has become an astrophysicsal laboratory to study subtle thermodynamic properties of a Coulomb system under conditions that cannot be acheived on Earth.

One of the two major recent equation-of-state and opacity efforts is the international Opacity Project (OP; see the books by Seaton 1995, Berrington 1997). A necessary part of the OP is the so-called Mihalas–Hummer–Däppen (MHD) equation of state (see below). It deals with *heuristic* concepts about the modification of atoms and ions in a plasma. The principal effort of OP has been to construct a tremendous atomic database, comprising state-of-the-art theoretical and experimental data. The other major recent equation-of-state and opacity effort is being pursued by the OPAL group at Lawrence Livermore National Laboratory (Iglesias and Rogers 1996; Rogers *et al* 1996). Its equation of state is based on a sophisticated *systematic* method for including density effects in a plasma. A further effort is ongoing at Los Alamos National Laboratory, which has been an important opacity provider since the 1960s.

The equation of state

Chemical and physical picture

Most realistic equations of state that have appeared in the last 30 yr belong to the *chemical picture* and are based on the free-energy-minimization method. This method uses approximate statistical mechanical models (for example the nonrelativistic electron gas). From these models a macroscopic free energy is constructed as a function of temperature T, volume V and the particle numbers $N_1, \ldots, N_m$ of the m components of the plasma. This free energy is minimized subject to the stoichiometric constraint. The solution of this minimum problem then gives both the equilibrium concentrations and, if inserted in the free energy and its derivatives, the equation of state and the thermodynamic quantities.

In the absence of interaction terms, the free-energy minimization method is equivalent to the familiar Saha equation. For more realistic systems, interactions can be modeled in many ways. The MHD equation of state, *e.g.*, is based on an occupation probability formalism. Specifically, the internal partition functions $Z_s^{\rm int}$ of species s adopted by MHD are sums that are made convergent by weights

$$Z_s^{\rm int} = \sum_i w_{is} g_{is} \exp\left(-\frac{E_{is}}{k_B T}\right). \qquad (1)$$

Here, the index is labels the state i of species s. E_{is} and g_{is} are their energies (in MHD assumed to be unshifted) and statistical weights, respectively, k_B is the Boltzmann constant, T temperature and the weights w_{is} are the occupation probabilities that take into account charged and neutral surrounding particles. In physical terms, w_{is} gives the fraction of all particles of species s that can exist in state i with an electron bound to the atom or ion, and $1-w_{is}$ gives the fraction of those that are so heavily perturbed by nearby neighbors that their states are effectively destroyed.

In the alternative *physical picture*, on which the OPAL equation of state is based, no assumptions about

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

energy-level shifts or the convergence of internal partition functions have to be made. On the contrary, properties of energy levels and the partition functions come out from the formalism. The physical-picture approach is illustrated by the activity expansion for gaseous hydrogen. Pressure is determined from a self-consistent solution of the equations

$$\frac{p}{k_B T} = z + z^2 b_2 + z^3 b_3 + \cdots \tag{2}$$

$$\rho = \frac{z}{k_B T}\left(\frac{\partial p}{\partial z}\right). \tag{3}$$

In these equations, $z = \lambda^{-3}\exp(\mu/k_B T)$ is the activity, $\lambda \equiv h/(2\pi m_e k_B T)^{1/2}$ is the thermal (de Broglie) wavelength of electrons and μ is the chemical potential. The b_n are cluster coefficients such that b_2 includes all two particle states, b_3 includes all three particle-states, etc. Although the bound-state part of b_2 is divergent, the scattering-state part, which is omitted in the chemical-picture approach, has a compensating divergence. Consequently the total b_2 does not contain a divergence of this type.

Solar applications

In the solar convection zone, helioseismology presents an opportunity to isolate the question of the equation of state from opacity and nuclear reaction rates, since the stratification is essentially adiabatic and thus determined by thermodynamics. Accurate analysis of the observations requires use of the full, nonasymptotic behavior of the oscillations (see SOLAR INTERIOR: INVERSIONS OF HELIOSEISMIC DATA). Figure 1 shows a typical result of a numerical inversion of solar oscillation data. It gives, as a function of distance r from the center, the relative difference (in the sense Sun − model) between the squared sound speed obtained from inversion of oscillation data and that of two standard models. If a model were perfect, it would lead to a zero line. The two models used for figure 1 are in all respects identical except that they use a different equation of state (MHD and OPAL).

In a simplifying spirit we can look at results such as shown in figure 1 as the *data* of helioseismology, disregarding how they were obtained from solar oscillation frequencies. The most important result of the helioseismic equation-of-state analyses was that it is essential to include the leading Coulomb correction to ideal-gas thermodynamics. Under solar conditions, the size of the relative Coulomb pressure correction is largest in the outer part of the convection zone (about 8%) and it has another local maximum in the core (about −1%). Figure 1, however, hides the fact that the Coulomb correction is the most important one, since both MHD and OPAL already contain it. Note that in figure 1 the most significant information about the equation of state regards the convection zone ($r > 0.71 R_\odot$), since, beneath it, one cannot disentangle the influence from the equation of state from other effects. Figure 1 contains the evidence that in the region $0.90 R_\odot < r < 0.97 R_\odot$ the OPAL equation of state is a better fit to reality than MHD.

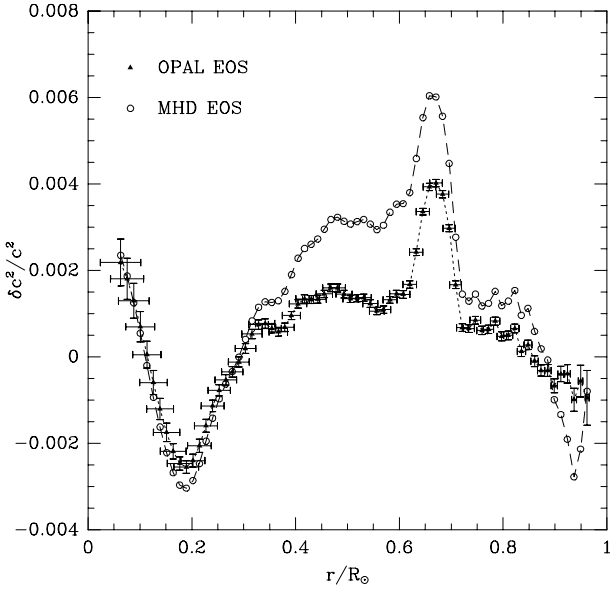

Figure 1. Difference between squared sound speed from inversion of oscillation data and that of a standard model based on the MHD (circles) and OPAL (triangles) equation of state. Figure provided by S Basu (Princeton).

Two very recent inversions have had further implications for the equation of state. First, the strong constraints from helioseismology now force us to include *relativistic effects* of electrons. Neither MHD nor OPAL has so far included relativistic effects, unlike the earlier and simpler EFF and its more recent sibling SIREFF (see below). Second, there are indications that, for $r > 0.97 R_\odot$, MHD is favored over OPAL. If this result is confirmed, it would mean that the treatment of excited states in equation (1) is validated. Such a result might appear somewhat surprising, because in the upper part of the Sun, with density decreasing, OPAL by its nature of a systematic expansion is becoming inevitably more accurate; however, by its heuristic approach MHD would have incorporated even finer, higher-order effects. Since the excited states are effective in the hydrogen and helium ionization zones, this result would have implications for the solar helium abundance determination.

Opacity

History

Opacity has long been an issue in understanding stars. As long ago as 1926, Eddington identified opacity as one of two clouds obscuring stellar model calculations (the other being the source of stellar energy). At that time it was thought that bound–bound absorption was not a significant source of opacity. It was another 40 yr before a group at Los Alamos included bound–bound transitions and obtained increases in the Rosseland mean opacity[1]

[1] The Rosseland mean is a weighted frequency average over the inverse opacity.

exceeding a factor of 3 in some cases. The Cox–Stewart opacities greatly improved the quality of stellar models and remained the standard for more than a quarter century.

Even though the Los Alamos opacities helped elucidate many features of stars, a number of observations continued to resist explanation. For example, period ratios in classical Cepheid models were too low, the mechanism for pulsation in β-Cephei stars could not be identified, the calculated Li abundance in dwarf stars of the Hyades cluster was much less than observed and simulations underestimated wind-driven mass loss in classical novae. A number of studies found that these problems are sensitive to changes in opacity. However, the opacity increases needed seemed unrealistically large, as much as 300% in the case of the classical Cepheids and the β-Cephei stars. This situation has spawned the major opacity recomputation efforts by OP and OPAL, which have now been ongoing for 15 yr. The new calculations of both groups have resulted in the expected large opacity increases, and they have helped resolve a number of long-standing puzzles.

Solar applications

The opacity affects the thermal structure of a star and therefore the sound speed and density stratification. Thus observations of solar and stellar pulsations have the potential to constrain and test opacity calculations. It is important to note, however, that helioseismology alone cannot determine the thermal stratification and hence the opacity, without additional assumptions. The oscillation frequencies are sensitive only to the mechanical structure of the star, particularly the sound speed c. The helioseismic inferences can only provide a combination of the opacity and the composition profile, but not each of these properties separately. Only if the composition profile is otherwise determined, e.g. from a stellar evolution calculation, can the opacity be properly constrained from the helioseismic data. Such successes were indeed possible; already with early inversions for the solar sound speed done in the mid 1980s, it resulted that a modest increase in opacity, around 20% at temperatures between about 2×10^6 K and 5×10^6 K, was required relative to the Los Alamos opacity tables used then. Such an increase has indeed resulted from the more recent (OPAL) opacity calculations. Interestingly, this trend now appears to be reversing: the latest updates to the OPAL opacities and the solar initial composition have tended to increase the discrepancies between the Sun and the model.

Practical considerations

Opacity and equation of state data can be in the form of either analytical or in-line routines that calculate the desired opacities or thermodynamic quantities, given as input the temperature, density and chemical composition. Alternatively, pre-calculated opacity and equation of state tables can be provided, with appropriate look-up and interpolation routines. The hydrostatic structure calculation requires fewer thermodynamic quantities or derivatives than a pulsation calculation, for which smooth derivatives of the various quantities are required.

There are advantages and disadvantages of using tables versus in-line analytical formulations. Tables are often limited in coverage of T, ρ and composition space, and so may not be useful for stellar models over a wide range of masses, compositions and evolutionary states. Interpolation within and between tables or extrapolation off the edges of tables can be difficult and risky, and introduces significant uncertainty into the calculations. On the other hand, tables often include superior physics compared with simple analytical schemes and can be less computationally expensive than a sophisticated analytical routine.

Analytical procedures can be more flexible, for example in taking into account variations in element mixtures and composition or in providing smooth derivatives. They also may be modified easily to generate additional thermodynamic quantities. Analytical procedures can also be useful to explore the importance of various physical processes, since these processes can easily be turned on and off, exaggerated with multipliers, etc.

Selected equations of state

Table 1 lists the specifications of four of the more popular equations of state. For more information, see the article by Däppen and Guzik (1999), which contains a more detailed description of these, and other equations of state. The equations of state of table 1 are the Eggleton, Faulkner and Flannery (EFF) formalism, the EFF extension by Swenson, Irwin and Rogers (SIREFF), MHD and OPAL. Documentation of the MHD equation of state is found in the book by Seaton (1995). The newest OPAL equation of state tables are described in the article by Rogers *et al* (1996).

Mid- to high-temperature opacities

The three currently most popular opacity sources are listed and the reader is again referred to the article by Däppen and Guzik (1999) for further details and other opacities.

- The updated OPAL tables (Iglesias and Rogers 1996) are based on a 21-element solar mixture. The tables span the range $3.75 \leq \log T \leq 8.7$, and $-8 \leq \log R \leq +1$, where $R = T_6^3/\rho$ and $T_6 = 10^{-6}T$. These opacities and interpolation routines are available on the web site `http://www-phys.llnl.gov/V_Div/OPAL/`.
- The OP provides monochromatic opacities for 17 astrophysically relevant elements up through Ni, on grids of T and N_e (electron density). Tables of Rosseland and Planck[2] mean opacities for 213 compositions are available. Interpolation codes and tables are available on the web site of the OP `http://visier.u-strasbg.fr/OP.html`.
- Los Alamos has recently generated new opacities, using the so-called LEDCOP (Los Alamos Light Element

[2] The Planck mean is a weighted frequency average over the opacity.

Quantum diffraction	No	No	Yes	No

[a] Debye-Hückel approximation.
[b] *Ad hoc*.
[c] *Ad hoc*, but more general than in EFF.
[d] Molecules will be included in future OPAL tables.

Detailed Configuration Opacity) code. The new Los Alamos Astrophysical Opacity database contains elements from hydrogen to zinc (atomic number $Z = 1$–30). The individual element data can be manipulated to generate Rosseland or Planck mean opacities for any desired mixture. The ranges of validity in T and ρ are 0.5 eV $< T <$ 100 keV, and 10^{-10} g cm^{-3} $\leq \rho \leq 10^9$ g cm^{-3}. These codes and tables are available on the web site `http://t4.lanl.gov`. These new Los Alamos opacities have not yet been tested extensively for astrophysical applications, but a direct comparison with OPAL opacities reveals that they are much closer to OPAL than to the older Los Alamos opacities. Figure 2 shows a selected comparison of OPAL, LEDCOP and OP opacities for stellar interior conditions. It emerges that the results of these three modern efforts agree quite well with each other, but small differences remain.

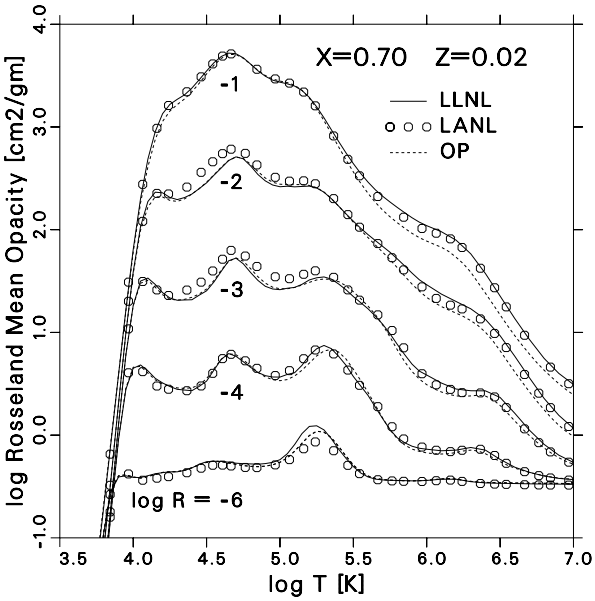

Figure 2. OPAL (Livermore), LEDCOP (latest Los Alamos) and OP Rosseland mean opacities versus temperature for $X = 0.7$ and $Z = 0.02$, for several log R values, where $R = \rho/T_6^3$. Figure provided by J J Keady (Los Alamos).

Low-temperature opacities

Note that neither the OPAL nor OP opacities extend to low temperatures or include molecules. Also, it may be more correct to use Planck mean opacities for optically thin outer layers. For this reason, modelers of the Sun and low-mass stars must supplement the OPAL or OP tables with low-temperature opacities. The article by Däppen and Guzik (1999) lists the current options. The two most important are as follows.

- Kurucz provides Rosseland mean opacities including 58 million lines and diatomic molecules for $1 > \log(Z) > -3$ relative to solar, based on the Grevesse solar mixture (data available at the web site `http://cfaku5.harvard.edu/OPACITIES`).
- Alexander and Ferguson provide Rosseland and Planck mean opacity tables valid for $T = 700$–12 500 K including atomic and molecular line absorption, grain absorption and scattering by silicates, iron, carbon and SiC (contact Alexander, e-mail: `dra@twsuvm.uc.twsu.edu`).

Solar Interior: Influence of Magnetic Fields

The p-modes that propagate in the solar interior are sound waves in a gravitationally stratified medium (see SOLAR INTERIOR; HELIOSEISMOLOGY: THEORY). Sound waves involve compressions and rarefactions of the medium and as such are influenced by other effects that cause pressure variations. Magnetic fields impart an extra degree of elasticity to a medium. In the plasma that models the Sun and its atmosphere, magnetic elasticity adds to the compressibility of the medium. These general considerations lead us to expect a coupling between the Sun's global oscillations (p-modes) and magnetism. What is the nature of that coupling and how may it be used to further our understanding of both oscillations and solar magnetism? This is the topic of magnetic helioseismology; still at an early stage of observational and theoretical development, the subject promises to provide insights not only into the physics of the Sun's global oscillations but also into the nature of some of its magnetic structures.

In what ways, then, may magnetism influence p-mode oscillations? An equilibrium magnetic field carries with it a magnetic pressure and a magnetic tension (see MAGNETOHYDRODYNAMICS); when perturbed, the field generates restoring forces through the bending or compressing of its field lines, which lead to magnetohydrodynamic waves (see MAGNETOHYDRODYNAMIC WAVES). Magnetoacoustic waves are produced whenever perturbations compress or expand the medium. Thus p-modes, being compressible, are quite naturally influenced by magnetism.

Structured magnetism

Now the Sun's magnetic field is not distributed uniformly through its interior, surface and atmosphere; rather, the field tends to be accumulated in certain locations favored by stability considerations or the influence of convective flows. In the surface layers of the Sun, magnetism is most apparent in sunspots where the field conspires to produce a 20% or 30% local cooling of the plasma when compared with surroundings (see SUNSPOTS). Aside from sunspots, magnetism is also present in small magnetic flux tubes which border the network between supergranules, preferring the downdraught regions (see SOLAR PHOTOSPHERE). Thus, the field of the photospheric layers of the Sun is present in concentrated forms, rather than spread uniformly throughout the medium: flux tubes or ensembles of flux tubes are the preferred forms.

Above the photosphere, the fall off in plasma pressure brought about by gravitational stratification allows the confined fields of flux tubes to spread out and occupy the whole of the atmosphere. The expansion of the field is accomplished by some 1000–1500 km above the solar surface. The result is a magnetic canopy. The canopy overlies the photosphere and separates magnetized plasma (in the overlying chromospheric and coronal atmosphere) from the convection zone and below (see CHROMOSPHERE: MAGNETIC CANOPY).

Below the photosphere, the roots of the magnetic field lie within the solar interior where various effects bring about the manipulation and transport of magnetic flux through the convection zone and into the visible layers (see SOLAR INTERIOR: CONVECTION ZONE FLUX TUBES). The base of the convection zone, some 200 000 km below the solar surface, is a favored location for the storage and manipulation of magnetic field.

Thus, it is convenient to view the magnetic field of the Sun in three separate locations: the solar interior, the vertical tubes of the photosphere, and the expanded field of the solar atmosphere.

These general considerations suggest that p-modes are influenced by magnetism, and that influence depends upon the local magnetism of the Sun. Thus there arises the possibility of a local seismology (see SOLAR INTERIOR: LOCAL HELIOSEISMOLOGY) in which p-modes interact with the magnetic fields of a particular region, producing a distinctive signature that may be analysed for information about the magnetic structure in question.

The influence of a magnetic field on p-modes may be thought of in several ways. First, the field modifies the equilibrium structure of a plasma, simply because its magnetic pressure has to be balanced along with the fluid or plasma pressure. Gradients in the total pressure (plasma plus magnetic) are balanced by gravitational effects: the medium is stratified according to magnetohydrostatic balance. Secondly, the presence of a magnetic field within a medium (plasma) means that additional forces act on the system when it is perturbed, and these forces depend upon the strength of the magnetic field. The effect is most simply characterized by the Alfvén speed, the basic speed with which a magnetic disturbance propagates, to be compared with the sound speed (the basic speed with which sound propagates in a medium). Together, these two speeds may be combined to describe a fast magnetoacoustic speed which is both supersonic and super-Alfvénic. Finally, there is an indirect effect possible because of magnetism: the temperature of the medium may be changed because of the presence of a magnetic field, thus modifying the sound speed. This effect is most clearly apparent in sunspots with their reduction in temperature (and thus sound speed), but may also occur elsewhere in more subtle ways.

Thus, the influence of magnetism on p-modes is different in different regions of the Sun. Sunspots offer locations where magnetism is especially significant; a 3000 G field in the visible layers of a sunspot produces a magnetic pressure that is broadly comparable with the atmospheric pressure of the plasma within the spot. Consequently, we can expect p-modes to be appreciably influenced by sunspots. Indeed, observations show that p-modes are strongly absorbed (up to 50%) in the vicinity of a spot (see SUNSPOT OSCILLATIONS AND SEISMOLOGY). Also, p-modes are influenced by the active regions that overlie sunspots; the amplitudes of oscillations are found to be

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

suppressed in the vicinity of active regions. Several theoretical interpretations have been advanced as possible explanations of the effect.

Elsewhere in the Sun, away from sunspots, the effects of magnetic fields on p-modes are likely to be less pronounced, either because the magnetic pressure in the field is considerably lower than the plasma pressure—as within the solar interior—or because the modes themselves do not reach that particular magnetic region (as with the solar corona). Generally, p-modes occupy the solar interior to different depths, depending upon the degree (a measure of horizontal wavelength) of the mode. Low-degree modes penetrate deeply below the solar surface, intermediate-degree modes are largely confined to within the convection zone, and high-degree modes occupy the upper reaches of the convection zone.

Now the solar interior is the store-house of all the magnetic field that is ultimately seen in the Sun's atmosphere. But, despite the obvious importance of the interior in the process of generating and manipulating magnetic field (see DYNAMOS: SOLAR AND STELLAR), the effects of subsurface magnetic fields on p-modes are not likely to be large. This is simply because stratification leads to a high plasma pressure in the interior, dominating any magnetic pressure that may be present. In fact, the field strength is uncertain in these layers. For example, estimates of the field at the base of the convection zone range anywhere from 10^3 G to 10^6 G; only field strengths towards the upper end of this range are likely to produce detectable effects on the oscillations. If fields of this order are present—and magnetic helioseismology can be expected to resolve this issue—then slight but significant changes in p-modes are to be expected as a consequence of such magnetism. Oscillations of low degree are perhaps most likely to be influenced by internal magnetic fields, since these modes penetrate deep within the Sun; modes of intermediate or high degree are confined mainly to the upper layers of the convection zone, and so are not directly subject to the fields stored deeper within the Sun. Instead, high-degree modes are likely to be influenced more by the fields that fill the chromosphere or are in photospheric flux tubes and sunspots.

Oscillations have also been used to probe active regions in the process of emerging through the convection zone. This is the developing subject of solar tomography. By looking at travel times of modes that occupy the upper 30% of the convection zone, it has proved possible to infer the existence of 'acoustic perturbations' at a depth of 10–20 Mm below the solar surface. The perturbations are in the mode propagation speed and amount to about ± 1.5 km s^{-1} in the magnetoacoustic speed, and are interpreted as corresponding either to local temperature changes or magnetism. At a depth of 10 Mm, the perturbation in propagation speed would correspond to a temperature variation of the order of 2000 K or a magnetic field of strength 15 000 G (or some combination of the two effects).

Solar cycle variations

Of particular interest in magnetic helioseismology is the observed variation of p-mode frequencies with the Sun's activity cycle (see SOLAR ACTIVITY). The effect was first suggested by data for low-degree modes (degrees 0–4) but the smallness of the effect (a frequency shift of about 1 part in 10^4) meant that it was not at first universally accepted. Later, detailed studies of both low- and intermediate-degree (5–140) modes showed unequivocally that oscillation frequencies vary with the solar cycle. Accurate ground-based measurements of low-degree modes are now available over an almost complete solar cycle of 22 years, and the period 1990 to 1996 (during which solar activity was falling) has been recently studied in detail. Also, observations from space, using instruments on the Solar and Heliospheric Observatory (SOHO) satellite, have monitored p-modes since 1996 (when the Sun was at a minimum in activity). Considerable interest attaches to expected developments in these programs as the Sun moves through solar maximum.

The analysis of frequency changes in time is done by comparing mode frequencies for one year with those in another year; systematic shifts are found. For example, frequencies measured when the Sun was at or close to solar minimum, such as in the year 1986, may be compared with frequencies measured in later years when the Sun was more active (e.g. 1988 and 1989). The shift in frequency may then be displayed as a function of frequency (taking, for example, the frequency at solar minimum as a base). The results show (see figure 1) that frequency shifts are very small for oscillations of frequency below about 2 mHz, but rise rapidly thereafter and reach a peak shift of about 0.8 μHz (for intermediate-degree modes) at a frequency just below 4 mHz. Thereafter, at higher frequencies the shift falls rapidly and may switch in sign. A similar trend is seen also in low-degree modes.

Theoretical explanations of the observed frequency shifts with the solar cycle have been based primarily upon a combination of temporal changes in chromospheric magnetism coupled with simultaneous changes in chromospheric temperature (i.e. changes in the magnetic canopy) or in changes in the magnetism and thermal structure of photospheric magnetic flux tubes. Such models give frequency shifts similar to those observed, but only at the expense of invoking thermal changes that are larger than expected. It may be that other effects, masquerading as temperature changes, are also involved.

Coronal seismology

Since p-modes are mainly confined to the solar interior they are not expected to be greatly influenced by the solar corona. Consequently, if we are to study the corona through seismology, it is unlikely that p-modes will be involved. Instead, a coronal seismology must be developed using waves other than p-modes as diagnostic probes. A number of such attempts are currently under way, using magnetohydrodynamic waves to probe the magnetism of the corona. Both propagating waves and

Dirac House, Temple Back, Bristol, BS1 6BE, UK

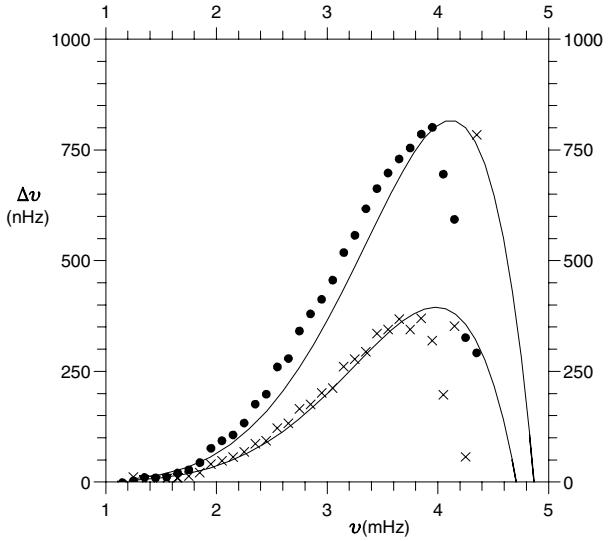

Figure 1. The observationally determined frequency shifts $\Delta\nu$ (in nHz) of intermediate p-modes as a function of frequency ν (in mHz) for the years 1988 (crosses) and 1989 (full circles), compared with 1986. The observations were made by K G Libbrecht and M F Woodard. Also shown are the results from model calculations by R Jain and B Roberts, for oscillations of degree 75. The theoretically determined frequency shifts (shown as full curves) arise from an increase in chromospheric magnetic field strength (from 30 G to 50 G (lower curve) or 61 G (upper curve)) combined with a simultaneous rise in chromospheric temperature (from 4170 K to 6370 K (lower curve) or 7770 K (upper curve)).

standing oscillations have been used in a variety of magnetic objects. Magnetic loops (see CORONAL LOOPS), plumes (see POLAR PLUMES), and prominences (see SOLAR PROMINENCE OSCILLATIONS) are all being investigated in an attempt to discover their properties through the use of a local seismology.

Solar Interior: Inversions of Helioseismic Data

Once the eigenfrequencies of the solar oscillations are measured (see HELIOSEISMIC OBSERVATIONS), they are analysed further to investigate the solar interior. For example, we can use these frequencies to reveal how the adiabatic soundspeed varies with depth, or how the interior of the Sun rotates differentially, both in depth and in latitude. This procedure is called *inversion*, because the procedure of calculating eigenfrequencies for a given solar structure, or a given rotation rate, is conventionally considered 'forward' (see HELIOSEISMOLOGY: THEORY). Inversions play the central role in our investigation of the solar interior, and indeed most of what we know about the internal structure of the Sun and its rotation (see SOLAR INTERIOR, SOLAR INTERIOR: ROTATION) have been obtained through inversions.

General properties

Generally, when there are many measurements (such as eigenfrequencies) which reflect a certain property (such as soundspeed distribution) of the system observed (such as the Sun), we can hope to infer this property in detail. How well we can do this depends on the actual information content of the entire dataset.

First of all, the information content of each measurement depends on how well the particular property is reflected in this measurement. The m-averaged eigenfrequencies ω_{nl} (n and l are the radial order and the degree of the mode) are determined by the (spherically averaged) distribution of soundspeed and density, but largely by the former in the case of p-mode oscillations. As a result, there is more information about the soundspeed distribution in the p-mode frequencies than about the density distribution. But a mode frequency can reflect only soundspeed distribution within the propagation zone of the mode; the frequency carries essentially no information about the soundspeed below the lower turning point. The statistical error in the measurement is also important; as the measurement error decreases the actual information content increases.

Another very important issue is how the information content of each measurement adds up; if the data are highly redundant, even if there are a large number of them, they do not add much independent information to each other. Consequently, although the effective measurement error will be lowered, the actual information content may not be rich enough for us to obtain much detail about the property we are investigating.

In case of inversions of solar oscillation frequencies, a certain degree of non-redundancy is guaranteed by the variation of the penetration depths from mode to mode, which ensures that the different modes sample different regions of the Sun, and therefore carry independent information.

Method of linear inversions

Helioseismic inversions are often linearized. In a typical linear inverse problem in one dimension ($a \le x \le b$), we seek to estimate a function $q(x)$ from a set of integral constraints

$$d_i = \int_a^b K_i(x) q(x)\,\mathrm{d}x + e_i \quad (i = 1, \ldots, M) \qquad (1)$$

where the measurement d_i, associated with error e_i, is linearly related to $q(x)$ with a kernel (or sensitivity function) $K_i(x)$, and M is the number of such measurements.

In fact, it is not possible to determine the function $q(x)$ uniquely if M is finite, even when the data are completely free from measurement error. This is because for any finite M, one can find an infinite number of functions that are orthogonal to $K_1(x) \ldots K_M(x)$, which, when added to $q(x)$, have no effect on the measurement. The dataset has no information about the component of $q(x)$ that is a linear combination of these functions, so this component has to remain undetermined. Fortunately, in helioseismic inversions these unknown components are generally highly oscillatory functions in space, so our lack of knowledge about their magnitude is unlikely to affect our global view of the Sun.

There are two important classes of inversion methods: optimally localized averaging (OLA) and regularized least-squares fitting (RLSF). Both are linear methods comprising only linear processes, and therefore produce an estimate of q at $x = x_0$, $\hat{q}(x_0)$, that is a linear combination of the data:

$$\begin{aligned}\hat{q}(x_0) &= \sum_i c_i(x_0) d_i \\ &= \int_a^b D(x; x_0) q(x)\,\mathrm{d}x + \sum_i c_i(x_0) e_i\end{aligned}$$

where $c_i(x_0)$ is inversion coefficient and

$$D(x; x_0) \equiv \sum_i c_i(x_0) K_i(x)$$

is the averaging kernel, the width of which gives the resolution of the estimate; if $D(x; x_0)$ is sharply peaked at $x = x_0$, then $\hat{q}(x_0)$ will be close to $q(x_0)$ but for the error term. The standard deviation of the estimate $\hat{q}(x_0)$ is given by

$$\delta\hat{q}(x_0) = \left(\sum_i c_i(x_0) c_j(x_0) E_{ij} \right)^{1/2}$$

where E_{ij} is the covariance of e_i and e_j. It would be desired that the resolution be as high as possible and that the error be as low as possible, but in fact there is a trade-off between the two; a higher resolution is generally associated with greater amplitudes of the coefficients $c_i(x_0)$, and hence with greater error (figure 1).

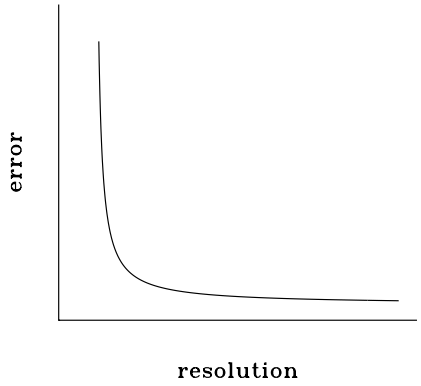

Figure 1. A schematic figure of a trade-off curve.

Optimally localized averaging (OLA)
The optimally localized averaging technique directly seek to balance resolution and error by minimizing, for example,

$$S_{\rm OLA} = \int_a^b D(x;x_0)^2 (x-x_0)^2 \,{\rm d}x + \alpha[\delta\hat{q}(x_0)]^2$$

for each target position x_0, subject to the unimodular condition

$$\int_a^b D(x;x_0)\,{\rm d}x = 1$$

by varying $c_1(x_0)\ldots c_M(x_0)$. Significant amplitudes in $D(x;x_0)$ far from $x = x_0$ are penalized by the integral, a measure of spread of the averaging kernel, whereas a large error is penalized by the second term. The trade-off parameter α determines the compromise between the two. As the data error increases, a higher value of α will have to be chosen and as a result, $D(x;x_0)$ will be more poorly localized. When the localization is poor, often the center x_1 of $D(x;x_0)$ is calculated under a proper definition (e.g. the center of gravity), and $\hat{q}(x_0)$ is re-interpreted as $\hat{q}(x_1)$.

Using a different measure of spread will lead to a different formalism. An essential and important alternative, however, is so-called subtractive optimally localized averaging (SOLA), in which the averaging kernel is fit to a target function (e.g. Gaussian) centered at the target position.

Regularized least-squares fitting (RLSF)
To many people, probably the most natural way to solve the set of equation (1) is to use least-squares fitting; to find an estimate $\hat{q}(x)$ one minimizes

$$S_{\rm LSF} = \sum_i \frac{1}{e_i^2}\left(d_i - \int_a^b K_i(x)\hat{q}(x)\,{\rm d}x\right)^2.$$

In practice, $\hat{q}(x)$ is expanded in a series of functions and then the minimization problem is reduced to a matrix equation. It is often found, however, that the resulting matrix is nearly singular, producing an 'ill-posed' problem. This is normally caused by the redundancy of the data. The most common way to avoid this is to introduce a 'regularization' term that imposes some kind of smoothness to the estimates $\hat{q}(x)$. For example, minimization of

$$S_{\rm RLSF} = S_{\rm LSF} + \alpha \int_a^b [\mathcal{L}q(x)]^2\,{\rm d}x,$$

where α is a regularization parameter and $\mathcal{L}$ is a differential operator, leads to a linear system of equations that is not singular, provided α is large enough. Unlike OLA, it is not necessary to obtain inversion coefficients explicitly, but they are often calculated for diagnostic purposes.

Structure inversion

Since the spherically averaged structure of the Sun determines the m-averaged eigenfrequencies ω_{nl}, in *structure inversion* the observed spectrum of the m-averaged frequency is inverted to recover the internal structure of the Sun.

The m-averaged frequencies of a solar model are calculated by solving an eigenvalue problem. Although this is almost routine work today, its complexity, and nonlinear nature in particular, does not permit direct inversions. Therefore we have to introduce some approximation to simplify the forward problem, so that the problem becomes directly invertible.

One strategy is to use asymptotic analysis. From the asymptotic analysis of solar p-mode oscillations, we see that the m-averaged frequency ω is related to $c(r)$, the soundspeed as a function of radial coordinate r, in the following way:

$$\int_{r_t}^R \left(1 - \frac{L^2c^2}{r^2\omega^2}\right)^{1/2} \frac{{\rm d}r}{c} = \frac{\pi(n+\alpha)}{\omega}$$

where r_t is the radius of the lower turning point determined by the relation $c(r_t)/r_t = \omega/L$, R is the solar radius and $L = \sqrt{l(l+1)}$. The phaseshift α is generally a function of frequency, but in the simplest treatment it is regarded as a constant. We note that, for a given soundspeed distribution, the left-hand side is a function of $w \equiv \omega/L$ alone, and denote this function by $F(w)$, which is identified to the observed quantity in the right-hand side. Then the relation

$$\int_{r_t}^R \left(1 - \frac{L^2c^2}{r^2\omega^2}\right)^{1/2} \frac{{\rm d}r}{c} = F(w)$$

is analytically inverted to yield

$$r = R\exp\left[-\frac{2}{\pi}\int_{a(R)}^{a(r)} \left(\frac{1}{w^2} - \frac{1}{a^2}\right)^{-1/2} \frac{{\rm d}F}{{\rm d}w}\,{\rm d}w\right]$$

where $a(r) \equiv c(r)/r$ is a monotonically decreasing function of r in the solar case. This formula gives the depth as a function of a, which can easily be converted to

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

the soundspeed distribution $c(r)$. In reality, $F(w)$ can be observationally constructed only in a limited range: even for the highest degree modes, w is larger than $a(R)$, the surface value, and therefore $F(w)$ cannot be known down to $a(R)$. A minor correction term is usually introduced to amend this. Likewise, the highest observed $w = \omega/L$ determines the deepest layer of the Sun which is accessible by this method.

Although the accuracy of the asymptotic method is limited by the accuracy of asymptotic analysis itself, the method proved to be very successful. More sophisticated asymptotic analyses, which can also be used for inversion, have been developed.

Another strategy, which is more commonly adopted nowadays, is to abandon the idea of dealing with frequencies themselves. Instead, we consider the difference between solar frequencies $\omega_{\rm sun}$ and the frequencies of our reference model, $\omega_{\rm ref}$ (the suffixes n and l are omitted). If we assume that our reference model is close enough to the Sun, then we can use linear perturbation theory to relate the difference in structures to difference in frequencies:

$$\frac{\delta\omega}{\omega} = \int_0^R \left(K_{c,\rho}(r)\frac{\delta c}{c}(r) + K_{\rho,c}(r)\frac{\delta\rho}{\rho}(r) \right) \mathrm{d}r + E^{-1}\mathcal{F}_{\rm surf}(\omega)$$

where $\delta\omega = \omega_{\rm sun} - \omega_{\rm ref}$, ω is normally taken to be $\omega_{\rm ref}$, $K_{c,\rho}(r)$ and $K_{\rho,c}(r)$ are the kernels calculated from the reference model (figure 2), δc and $\delta\rho$ denote the excesses in soundspeed c and density ρ in the Sun, respectively, with respect to the reference model. The extra term is present because of our poor knowledge of the surface layers of the Sun; E is the normalized mode inertia and $\mathcal{F}_{\rm surf}$ is the surface term. Choices of quantities other than c and ρ are possible too.

Once the forward problem is linearized in this way, it can be inverted by using either OLA or RLSF. The formulation in the previous section requires some modifications because the number of variables is two in this case, and also because of the presence of the surface term. In the case of RLSF, having two variables requires that the two functions have to be fitted at the same time. In the case of OLA, one of the variables (say, soundspeed excess) is chosen as the target, and to $S_{\rm OLA}$ is added an extra term that penalizes contributions from the other variable.

The surface term has to be evaluated from the comparison between $\omega_{\rm sun}$ and $\omega_{\rm ref}$ and then subtracted from the left-hand side. This can also be done implicitly in the case of OLA, by choosing the coefficients in such a way that the contribution from the surface term vanishes.

Rotation inversion

The internal rotation of the Sun manifests itself in the variation of eigenfrequency over azimuthal order m. In *rotation inversion*, we invert the rotational splitting, the shift of frequency from the m-averaged value $\omega_{nlm} - \omega_{nl}$, for internal differential rotation of the Sun. The rotational splitting is usually calculated by using linear perturbation theory, noting that the Sun's rotation rate is slow compared with its oscillation frequencies. The result is a linear relation between solar internal rotation and rotational splittings:

$$\frac{\omega_{nlm} - \omega_{nl}}{m} = \int_0^R r\,\mathrm{d}r \int_0^\pi \mathrm{d}\theta\, K_{nlm}(r,\theta)\Omega(r,\theta)$$

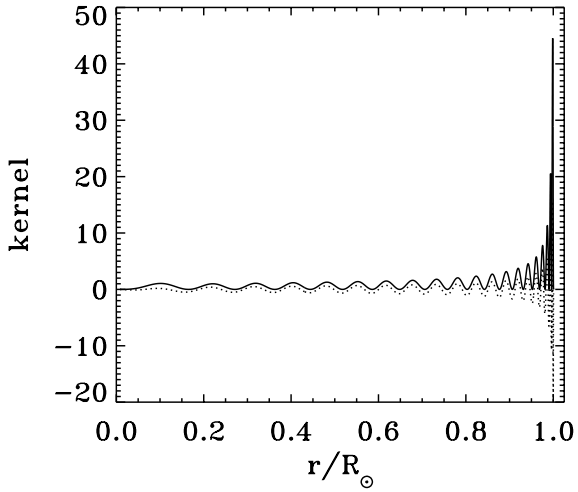

Figure 2. The kernels $K_{c,\rho}(r)$ (full curve) and $K_{\rho,c}(r)$ (dotted curve) calculated from a standard model for $l = 1$, $n = 20$ mode.

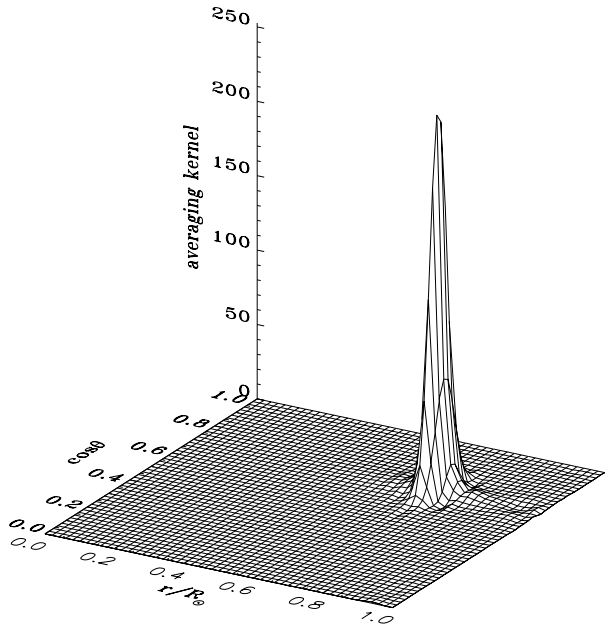

Figure 3. An example of a well localized averaging kernel for two-dimensional rotation inversion. The target position is $r/R_\odot = 0.75$, colatitude $\theta = 45^\circ$.

which is numerically invertible. This is similar to the second approach of structure inversion: here we use the linearized difference between eigenfrequencies of a rotating Sun and with frequencies of a non-rotating Sun to infer the difference (namely the rotation). In this case, the linear inversion methods discussed before are more readily applicable except for the difference in dimensions. Figure 3 illustrates an averaging kernel constructed by an OLA method.

Solar Interior: Local Helioseismology

This article describes how we use acoustic waves to study the subsurface properties of particular areas of the Sun. Local helioseismology is not as well developed as the more mature area of study, global HELIOSEISMOLOGY. New techniques are still being suggested and developed.This article will discuss some of these techniques and the most solid of the inferences about the SOLAR INTERIOR derived from them.

When one observes a spectral line formed in the SOLAR PHOTOSPHERE, one finds that the wavelength shifts back and forth with a period of about 5 min. This wavelength shift is caused by the DOPPLER EFFECT and tells us there is an approximately vertical mass motion in the photosphere of several hundred m s^{-1}. Theoretically it was calculated some years ago that acoustic waves with 5 min period should not propagate in the sun's photosphere. In fact, by measuring the Doppler shift at different heights in the photosphere, it was found that the waves are not propagating, but that the whole atmosphere is lifting up and down.

From calculations we know that acoustic waves of 5 min period propagate throughout most of the interior of the Sun, but that near the photosphere, where the density is falling off rapidly, the waves reflect. So the interior of the Sun can be considered as a cavity allowing acoustic wave propagation. As part of this reflection process, the atmosphere is raised and lowered with the period of the wave, leading to our observations of Doppler shifts in the photosphere.

By observing different locations in the photosphere, we obtain a picture of apparently independent oscillators, separated by roughly the acoustic wavelength in the photosphere, 2 Mm. The oscillators are not very good ones, with the amplitude rising and falling and the frequency varying.

Below the surface, waves propagate away from a source near the surface. The waves follow ray paths, as seen in figure 1. For a wave propagating into the interior obliquely, the increasing temperature (and hence increasing sound speed) causes the ray paths to bend, or refract. At some point the rays are bent back toward the surface which can be called total internal refraction, similar to the optical phenomenon of total internal reflection. The bottom of the ray path, or turning point, occurs at a characteristic depth. From a straightforward examination of the purely acoustic dispersion relation, we find that the sound speed at the bottom of the ray path is the same as the horizontal phase speed seen at the surface (ω/k_{h}), where ω is the frequency and k_{h} is the horizontal wavenumber. An important point to remember is that, when we observe a wave with phase speed ω/k_{h}, that wave propagates to a depth at which the sound speed is the same as the phase speed.

From a variety of evidence, we believe that the acoustic waves are excited by convective motion just below the photosphere.The lifetime of this convection, visible at the surface and called GRANULATION, is about 15 min. One possible picture of the wave field is a random array of sources sending off wave packets with 5 min period (the turnover time of the convection) and lasting for about 15 min. This random array of sources could very densely cover the solar surface or not—we do not know yet. The basic problem of local helioseismology is how to use these waves as a probe of solar structure.

One way to use these waves is to somehow isolate the waves travelling from one surface location to another. Two methods have been studied that perform this isolation, termed time–distance helioseismology and acoustic imaging.

In time–distance helioseismology, the signals at two surface locations are cross correlated, a mathematical operation consisting of shifting in time the two signals relative to each other and measuring how similar the two signals are at each value of the shift.

If a wave packet was emitted at surface location 1 at time t and it takes an interval T to travel along the subsurface path to location 2, we expect that the signal at location 2 at time $t + T$ would be most similar to the signal at location 1. The time interval T, called the travel time, depends on the distance between the locations, with T increasing with the separation. T therefore depends on the normal increase of sound speed with depth into the Sun. It also depends on temperature perturbations, flows and magnetic fields along the way. If there is a 'hot spot' along the waves' path, the wave will temporarily speed up and the resultant interval T will be reduced. If there is a material flow, say from a convective cell, with the flow directed towards location 2, the wave will be advected by the flow and the resultant interval T will be reduced. Conversely, for waves travelling from location 2 to location 1, the interval T_{21} will be increased. So, by measuring the difference in travel time for the two directions, the direction and magnitude of flows can be isolated.

The second method of isolating the waves is called acoustic imaging. An acoustic signal present at a certain location and a certain time will act like a source. The signal will propagate out from the origin and at a certain time interval later will reach the surface. In principle, all surface points can be used and it is only necessary to know how long it takes to propagate to each surface point. Then, by shifting the signals in time and adding them up over all the surface points, we can reproduce the signal at the origin. What we have described here is the generation of the origin signal from the outgoing waves. However, the process can be reversed and the signal can be reconstructed from the ingoing waves. That is, we look earlier in time at waves that will propagate to the origin point.

The reconstructed signals, ingoing and outgoing, contain information about flows, magnetic fields, temperature perturbations and absorption. To date, information about absorption and phase changes has been derived. By comparing the strength of the ingoing signal, which is unaffected by whatever is at the origin, with the outgoing signal, which will be reduced in amplitude by an absorber

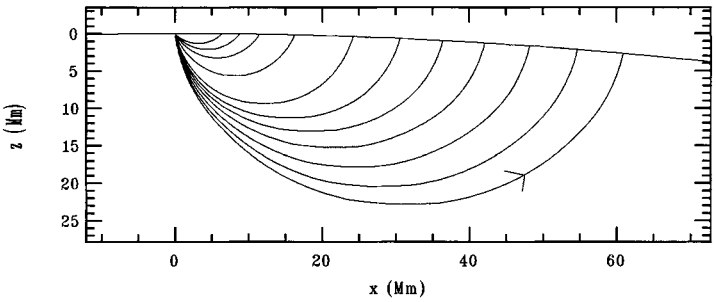

Figure 1. Acoustic ray paths below the solar surface. An acoustic source at the surface would send out energy along these paths that would return to the surface. It takes a longer time for waves to travel the longer paths.

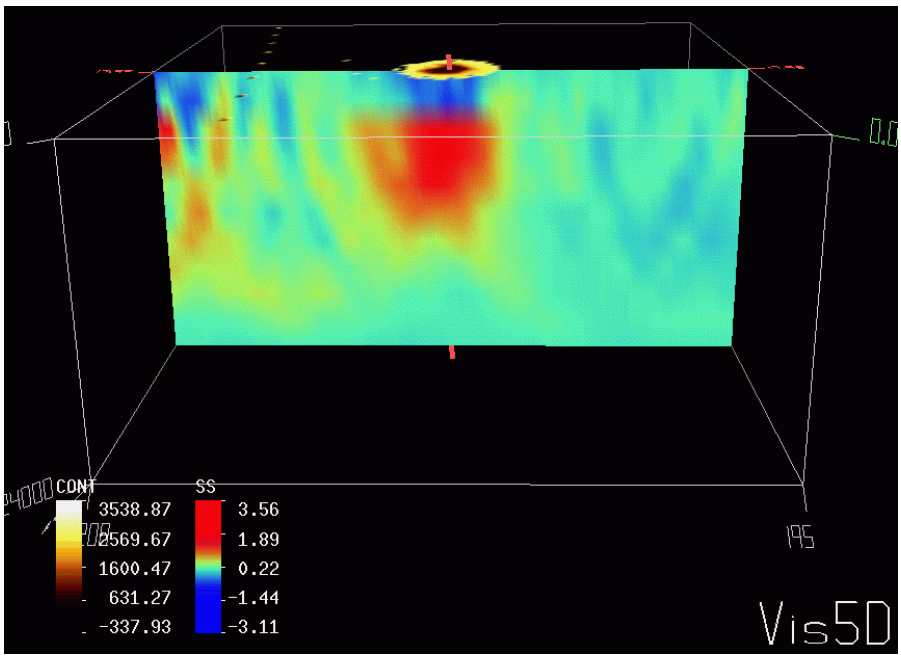

Figure 2. Subsurface wave speed map below a sunspot. One plane from a three-dimensional inversion is shown from the surface to 24 Mm below the surface. The top plane is the intensity of the sunspot at the surface with the normal surface intensity transparent. The wave speed perturbations are shown in the blue–red scale in km s^{-1}. **This figure is reproduced as Color Plate 51.**

near the origin, it has been possible to detect the presence of absorbers, mostly in the neighborhood of SUNSPOTS.

By cross correlating the ingoing signal with the outgoing signal, it is possible to find phase shifts that occur near the origin. These have been used to study the high-wave-speed region below sunspots. The high wave speeds are presumably caused by a combination of higher than normal temperature and magnetic field.

Both time–distance helioseismology and acoustic imaging can benefit from a further step of modelling or inversion. In this step the measurements, which are smoothed averages or integrals of interior solar properties, are used as input to a calculation that attempts to isolate the inhomogeneities at and below the solar surface. This is an important step that can better summarize our knowledge and uncertainties of the interior. To date, more of the modelling effort has centered on the time–distance technique, which has led to some interesting results as seen in the next section (see also SUNSPOT MODELS).

Examples

Sunspots have been observed with telescopes for nearly 400 yr. Our knowledge of their properties below the Sun's surface, or photosphere, is almost completely theoretical. We know that the gas in a sunspot is cooler than the surroundings, leading to the relative darkness and hence the name sunspot. We also know from our surface observations that a strong magnetic field permeates the sunspot (see SUNSPOT MAGNETIC FIELDS). An example of the intensity of a spot is shown in figure 2 in the top plane in which only the region of reduced brightness is shown. The black region, or umbra, is the region of maximum

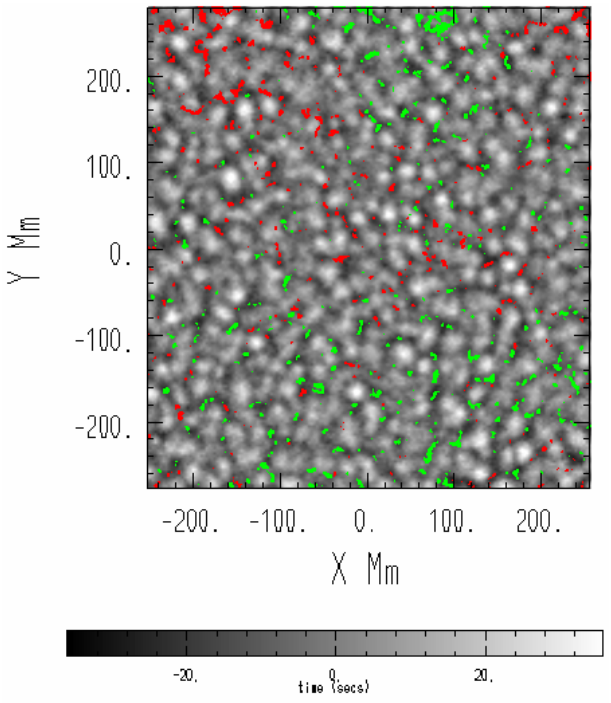

Figure 3. Divergence and magnetic field near the solar surface. The gray scale shows travel time measurements that are proportional to the velocity divergence, with white indicating outflow, black converging flow. The green and red are the two polarities of the magnetic field, which are only shown when the field is larger than 15 G. **This figure is reproduced as Color Plate 52.**

reduction of brightness. The region of intermediate brightness, the penumbra, is shown in red surrounding the umbra.

Below the intensity plane is shown a vertical cut from a three-dimensional wave-speed inversion using time–distance data. The most striking feature is the red region extending about 12 Mm below the sunspot indicating a region of higher than normal wave speed. Although in principle we may be able to separate temperature changes from magnetic fields, for this work it was not possible to distinguish the two. So, at a depth of 10 Mm, we have either a magnetic field of strength 10 kG or a temperature rise of 3% of the temperature.

The Sun's radiant energy, generated in the core by nuclear fusion, is carried outwards in the outer 30% of the radius by convective motions. These motions near the surface have been studied by time–distance helioseismic techniques. In figure 3, we show near-surface measurements of the flow of the supergranules, a cellular flow with cell sizes of 30 Mm. The gray scale in the figure is showing the flow divergence, positive or white for outflow and negative or black for converging flows. This signal was measured using surface-gravity waves concentrated in the 2 Mm immediately below the surface. Superposed on the divergence signal in green and red are areas where the magnetic field strength is larger than 15 G. The two colors are for the two polarities of the field. We see that the magnetic fields are concentrated in the regions of converging flows, as if the flows were pushing them around. The time–distance measurements provide a way to study this flow pattern in detail over most of the visible hemisphere, a definite improvement over other techniques.

Solar Interior: Neutrinos

Six experiments have observed solar NEUTRINOS, three of which are radiochemical experiments: Homestake (chlorine detector), GALLEX (gallium detector) and SAGE (gallium detectors). These radiochemical detectors register all neutrinos above a fixed threshold energy (0.8 MeV for chlorine, 0.2 MeV for gallium), with no further information about energy. Three other experiments, Kamiokande, SUPER-KAMIOKANDE, and SUDBURY NEUTRINO OBSERVATORY (SNO), measure the energies in real time of electrons produced in neutrino interactions in water. Kamiokande and Super-Kamiokande use neutrino–electron scattering in ordinary (but very pure) water and SNO uses neutrino absorption and neutrino disassociation of deuterium in heavy water. These water detectors are designed to measure electrons, from neutrino interactions, with more than 5 MeV of energy.

I will discuss the results of each of these experiments after I first answer a series of background questions. Why study solar neutrinos? What does the combined standard model (solar plus electroweak) predict for solar neutrinos? Why are the calculations of neutrino fluxes robust? What are the three solar neutrino problems? I will conclude by summarizing what have we learned in the first 35 yr of solar neutrino research and what we hope to learn in the next decade.

Why Study Solar Neutrinos?

Astronomers study solar neutrinos for different reasons than physicists. For astronomers, solar neutrino observations offer an opportunity to test directly the theories of STELLAR EVOLUTION and of nuclear energy generation. With neutrinos one can look into the interior of a main sequence star and observe the nuclear fusion reactions that are ultimately responsible for starlight via the general reaction

$$4\,^1\mathrm{H} \longrightarrow {}^4\mathrm{He} + 2\mathrm{e}^+ + 2\nu_\mathrm{e}. \qquad (1)$$

The optical depth of the Sun for a typical neutrino produced by nuclear fusion is $\sim 10^{-9}$, about 20 orders of magnitude smaller than the optical depth for a typical optical photon. As we shall see, solar neutrino experiments constitute quantitative, well-defined tests of the theory of stellar evolution. Since stellar evolution theory is used widely in interpreting astronomical observations, direct tests of this theory are of importance to astronomers.

Table 1 shows the principal nuclear reactions that accomplish equation (1) via the proton–proton chain of reactions. In what follows, we shall refer often to the reactions listed in this table.

Solar neutrinos are of interest to physicists because they can be used to perform unique particle physics experiments. Many physicists believe that solar neutrino experiments may have already provided evidence for a non-zero neutrino mass and that electron flavor (or the number of electron-type neutrinos) may not be conserved.

Table 1. The principal reactions of the p–p chain.

Reaction number	Reaction	Neutrino energy (MeV)
1	$\mathrm{p} + \mathrm{p} \rightarrow {}^2\mathrm{H} + \mathrm{e}^+ + \nu_\mathrm{e}$	0.0–0.4
2	$\mathrm{p} + \mathrm{e}^- + \mathrm{p} \rightarrow {}^2\mathrm{H} + \nu_\mathrm{e}$	1.4
3	${}^2\mathrm{H} + \mathrm{p} \rightarrow {}^3\mathrm{He} + \gamma$	
4	${}^3\mathrm{He} + {}^3\mathrm{He} \rightarrow {}^4\mathrm{He} + 2\mathrm{p}$	
	or	
5	${}^3\mathrm{He} + {}^4\mathrm{He} \rightarrow {}^7\mathrm{Be} + \gamma$	
	then	
6	$\mathrm{e}^- + {}^7\mathrm{Be} \rightarrow {}^7\mathrm{Li} + \nu_\mathrm{e}$	0.86, 0.38
7	${}^7\mathrm{Li} + \mathrm{p} \rightarrow {}^4\mathrm{He} + {}^4\mathrm{He}$	
	or	
8	${}^7\mathrm{Be} + \mathrm{p} \rightarrow {}^8\mathrm{B} + \gamma$	
9	${}^8\mathrm{B} \rightarrow {}^8\mathrm{Be} + \mathrm{e}^+ + \nu_\mathrm{e}$	0–15

For some of the theoretically most interesting neutrino parameters, solar neutrino experiments are more sensitive tests for neutrino transformations in flight than experiments that can be carried out with laboratory sources. The reasons for this exquisite sensitivity are (1) the great distance between the accelerator (the solar interior) and the detector (on Earth), (2) the relatively low energy (MeV) of solar neutrinos and (3) the enormous path length of matter ($\sim 10^{11}$ g cm^{-2}) that neutrinos must pass through on their way out of the Sun.

One can quantify the sensitivity of solar neutrinos relative to laboratory experiments by considering the proper time that would elapse for a finite-mass neutrino in flight between the point of production and the point of detection. The elapsed proper time is a measure of the opportunity that a neutrino has to transform its state and is proportional to the ratio, R, of path length divided by energy:

$$\text{proper time} \propto R = \frac{\text{path length}}{\text{energy}}. \qquad (2)$$

Future accelerator experiments with multi-GeV neutrinos are expected to reach a sensitivity of order $R = 10^2$ km GeV^{-1}. Reactor experiments are planned that will reach a level of sensitivity of $R = 10^5$ km GeV^{-1} for neutrinos with MeV energies. Solar neutrino experiments, because of the enormous distance between the source (the center of the Sun) and the detector (on Earth) and the relatively low energies (1 MeV to 10 MeV) of solar neutrinos involve much larger values of neutrino proper time,

$$R(\text{solar}) = \frac{10^8}{10^{-3}} \left(\frac{\text{km}}{\text{GeV}}\right) \sim 10^{11} \left(\frac{\text{km}}{\text{GeV}}\right). \qquad (3)$$

Because of the long proper time that is available to a neutrino to transform its state, solar neutrino experiments are sensitive to very small neutrino masses that can cause neutrino oscillations (changes between different neutrino states) in vacuum. Quantitatively, vacuum neutrino oscillations are sensitive to masses as small as

$$m_\nu(\text{solar level of sensitivity}) \sim 10^{-6}\ \text{eV}–10^{-5}\ \text{eV} \qquad (4)$$

provided that the electron-type neutrino that is created by beta decay contains appreciable portions of at least two different neutrino mass states. Technically, this amounts to saying that the mixing angle between different neutrino states is relatively large. Neutrino mixing is analogous to photon polarization in that photons can be in different polarization states (e.g. linear or circular) and there are mixing angles which describe the relations between the different states of the photon.

Laboratory experiments have achieved a sensitivity to electron-type neutrino masses of order 1 eV. Observations of neutrinos produced by COSMIC RAY interactions in the Earth's atmosphere have suggested the existence of neutrino oscillations involving neutrino mass differences of order ~0.07 eV.

Resonant neutrino oscillations, which may be induced by neutrino interactions with electrons in the Sun (the famous Mikheyev–Smirnov–Wolfenstein (MSW) effect), can occur even if the electron neutrino produced in the Sun is not well mixed with any of the other neutrinos (i.e. even if the mixing angles between e and μ neutrinos and between e and τ neutrinos are tiny). Standard solar models indicate that the Sun has a high central density, $\rho(\text{central}) \sim 1.5 \times 10^2$ g cm^{-3}, which allows electron-type neutrinos to be resonantly converted to the more difficult to detect μ or τ neutrinos by the MSW effect, provided that the difference in neutrino mass satisfies a resonance condition involving the local electron density and the neutrino energy.

Given the solar parameters from standard models, the planned and operating solar neutrino experiments are sensitive to neutrino masses in the range

$$10^{-4}\ \text{eV} \lesssim m_\nu \lesssim 10^{-2}\ \text{eV} \qquad (5)$$

via matter-induced resonant oscillations (MSW effect).

The range of neutrino masses given by equations (4) and (5) is included in the range of neutrino masses that are suggested by attractive particle-physics generalizations of the standard electroweak model.

Both vacuum neutrino oscillations and matter-enhanced neutrino oscillations can change electron-type neutrinos to the more difficult to detect μ or τ neutrinos. In addition, the likelihood that a neutrino will have its type changed may depend on its energy, affecting the shape of the energy spectrum of the surviving electron-type neutrinos. The shape of the energy spectrum for solar neutrinos produced by any particular nuclear process must be the same as the shape measured in the laboratory unless some new physics (e.g. neutrino oscillations) is occurring. Currently operating solar neutrino experiments will measure the shape of the energy spectrum.

What does the combined standard model tell us about solar neutrinos?

In this section, I will describe the combined standard model (standard solar model and standard electroweak theory) that is used to decide whether solar neutrino experiments have revealed something unexpected. Then I will present the calculated solar neutrino spectrum as predicted by the standard model.

The combined standard model

In order to interpret solar neutrino experiments, one must have a quantitative solar model. Unlike many other areas of astronomy in which one can make important discoveries by identifying new classes of objects (such as quasars, or x-ray sources, or γ-ray sources), solar neutrino research requires a reliable theoretical model for comparison with the observations in order to determine whether one has found something surprising. Our physical intuition is not yet sufficiently advanced to know whether we should be surprised by, for example, 10^{-2}, by 10^0 or by 10^2 neutrino-induced events per day in a chlorine tank the size of an olympic swimming pool.

I will use the most conservative model for comparison with experiments, the combined standard model, unless explicitly stated otherwise. The combined standard model is the standard model of solar structure and evolution and the standard electroweak model of particle physics (see also SOLAR EVOLUTION, STANDARD MODEL OF PARTICLE PHYSICS).

A solar model is required in order to predict the number of neutrinos created in a given energy range per unit time. On a fundamental level, a solar model is required in order to predict the rate of nuclear fusion by the p–p chain (shown in table 1 and discussed below) and the rate of fusion by the CNO reactions (originally favored by H BETHE in his epochal 1939 study of nuclear fusion reactions).

In our discussion, I will assume a result common to all modern solar models, namely that the CNO reactions contribute only a very small fraction of the luminosity of the Sun. Although the dominance of the p–p chain is often taken for granted in theoretical analyses of solar neutrino experiments, it is not an *a priori* obvious result.

A precise solar model is required to calculate accurately which nuclear reaction occurs more often at the two principal branching points of the p–p fusion chain. Referring to table 1, the branching points occur between reactions 4 and 5 and between reactions 6 and 8. If the p–p chain is terminated by reaction 4, only low-energy (<0.4 MeV) p–p neutrinos are produced, but if the termination occurs via reaction 5, then higher-energy ^{7}Be and ^{8}B neutrinos are created.

Many authors have claimed that the p–p neutrino flux is essentially determined by the solar luminosity. This is wrong. Depending on whether reaction 4 or reaction 5 is dominant, the flux of p–p neutrinos can vary by a factor 2. If reaction 4 is dominant, two p–p neutrinos are produced each time four protons are burned to produce an alpha particle (see equation (1)). If reaction 5 is dominant, only one p–p neutrino plus a ^{7}Be neutrino (or rarely a ^{8}B neutrino) is produced for each alpha particle that is formed. A solar model is required to decide which reaction, 4 or 5, is dominant.

The ratio of the rates for reaction 6 and reaction 8 determines how often ^{7}Be neutrinos (two lines: 0.86 MeV and 0.38 MeV) are produced rather than the rare, but more easily detected, ^{8}B neutrinos (maximum energy ~14 MeV) are produced. The predicted rates in solar neutrino experiments depend sensitively on the relative frequencies of these crucial reactions. Fortunately, the theoretical uncertainties in the predicted neutrino fluxes are not very large. For the important fluxes, the uncertainties vary from ~1% to ~20%, depending on the neutrino source in question. The rates for individual detectors are determined by the energy spectrum, by the neutrino type of the incoming solar neutrinos and by the interaction cross sections of the different detectors.

A particle physics model is required to predict what happens to the neutrinos after they are created. I will use the simplest version of the standard electroweak model, according to which nothing happens to the neutrinos after they are created in the interior of the Sun. In this theory, neutrinos are massless and neutrino flavor (electron type) is conserved. The standard electroweak model has had many successes in precision laboratory tests; modifications of this theory will be accepted only if incontrovertible experimental evidence forces a change.

The solar neutrino spectrum

Figure 1 shows the calculated neutrino spectrum for the most important neutrino sources from the Sun. I will discuss briefly the p–p (and pep) neutrinos, the ^{7}Be neutrinos, and the ^{8}B neutrinos. I will concentrate on the reliability of the predictions and will indicate the role of each of these neutrinos in the ongoing experiments.

The dominant source of solar neutrinos is the first reaction listed in table 1, the basic p–p reaction ($p + p \longrightarrow D + e^+ + \nu_e$), which creates neutrinos with energies less than 0.4 MeV. Most of the nuclear energy that emerges as sunlight begins with this reaction. The theoretical uncertainty in the p–p neutrino flux is about 1%. Among the solar neutrino experiments that are currently operating or that are being constructed, only the GALLEX and SAGE gallium experiments have energy thresholds low enough to detect the p–p neutrinos. About 0.2% of the p–p fusions are believed to occur via the pep reaction, the second reaction in table 1. This reaction produces a neutrino with a fixed energy, a 'neutrino line' that contributes a small part of the calculated event rate in the chlorine and gallium experiments.

The next most important source of neutrinos is from the ^{7}Be neutrino line at 0.86 MeV, which is produced by reaction 6 of table 1. About 15% of the solar luminosity is produced by reactions which go through this channel; the uncertainty in the neutrino flux is ~9%. The ^{7}Be neutrinos contribute significantly, according to standard model calculations, to the chlorine and the gallium experiments, but are too low in energy to be detected in the Kamiokande experiment. In an experiment under development called BOREXINO, ^{7}Be neutrinos will be detected by the unique signature they produce in scintillation light caused by neutrino–electron scattering.

The ^{8}B neutrino flux, produced by reaction 9 of table 1, is tiny, $\sim 10^{-4}$ of the flux of p–p neutrinos. However, the ^{8}B neutrinos are crucial for solar neutrino physics and astronomy. Because of their high energy (~10 MeV, which takes advantage of a superallowed transition from the nuclear ground state of chlorine to an excited state of argon), ^{8}B neutrinos dominate the predicted capture rate for the chlorine experiment. They are also the only significant source of neutrinos above the energy threshold in the water Cherenkov experiments, Kamiokande, Super-Kamiokande and SNO. Unfortunately, the theoretical uncertainty in the predicted ^{8}B neutrino flux is relatively large, ~19%.

Why are the predicted neutrino fluxes robust?

The predicted event rates in the different solar neutrino experiments have been remarkably stable over the past 30 yr. Our published estimate in 1968, which accompanied the first report by Davis and his collaborators of measurements with the chlorine experiment, was 7.5 ± 1.0 solar neutrino units (SNU); the most recent and detailed calculation yielded in 1998 a predicted rate of $7.7^{+1.2}_{-1.0}$ SNU. An SNU is a convenient unit to describe the measured rates of solar neutrino experiments: 10^{-36} interactions per target atom per second. The theoretical errors are intended to be as close as possible to effective 1σ errors; they are obtained by carrying out detailed calculations using 1σ uncertainties on all the measured input data and, for the theoretical errors (which are generally less important), by taking the extreme range of theoretical calculations to be 3σ uncertainties.

In the intervening three decades since the first experimental report on solar neutrinos, my colleagues and I have calculated many different models with steady improvements in measured and calculated input data and in the physics used to describe the solar interior. The best-estimate predictions have bounced around every few years, as different improvements were included, but the answers have always remained within ± 2 SNU of the 1968 best estimate.

There are three reasons that the theoretical calculations of the neutrino fluxes are robust: (1) the availability of precision measurements and precision calculations of input data; (2) the connection between neutrino fluxes and the measured solar luminosity; (3) the measurement of the helioseismological frequencies of the solar pressure-mode (p-mode) eigenfrequencies.

Over the past three decades, many hundreds of researchers have performed precision measurements of crucial input data including nuclear reaction cross sections and the abundances of the chemical elements on the solar surface. Many other researchers have calculated accurate opacities, equations of state and weak interaction cross sections. By now, these input data are relatively precise and their uncertainties are quantifiable.

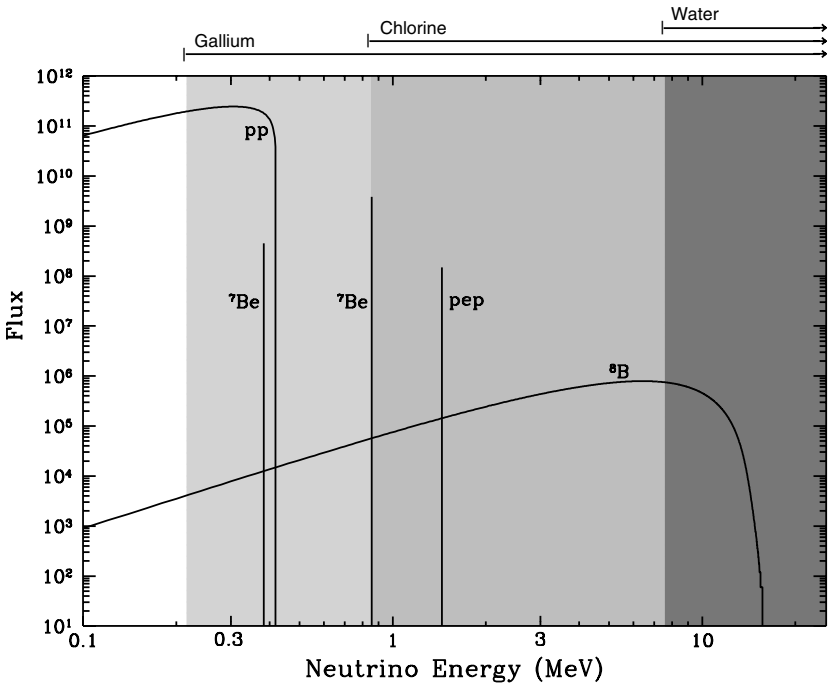

Figure 1. Solar neutrino spectrum. This figure shows the energy spectrum of neutrinos from the p–p chain that is predicted by the standard solar model. The neutrino fluxes from continuum sources (p–p and ^{8}B) are given in the units of number per cm^2 per second per MeV at 1 astronomical unit. The line fluxes (pep and ^{7}Be) are given in number per cm^2 per second. The arrows at the top of the figure indicate the energy thresholds for the ongoing neutrino experiments. The higher-energy ^{7}Be line is just above threshold in the chlorine experiment. For simplicity, CNO neutrinos are omitted.

The solar neutrino fluxes and the solar luminosity both depend on the rates of the nuclear fusion reactions in the solar interior. Since we know experimentally the solar luminosity (to an accuracy of ∼0.4%), the calculated neutrino fluxes are strongly constrained by the fact that the standard solar models must yield precisely the measured solar luminosity.

Thousands of p-mode helioseismological frequencies have been measured to an accuracy of 1 part in 10^4. The standard solar models discussed here reproduce these p-mode frequencies to an rms accuracy of better than 1 part in 1000. In fact, the standard solar models are in agreement with the measured helioseismological frequencies to a high level of precision without any adjustment of parameters.

The calculated solar neutrino fluxes are, after 30 yr of intense study, known to reasonable accuracy because of the many precise measurements and calculations of input data, because of the strong constraint imposed on the models by the measured total solar luminosity and because of the important tests of solar structure that are provided by helioseismological measurements (see HELIOSEISMIC OBSERVATIONS).

What are the three solar neutrino problems?

I will compare in this section the predictions of the combined standard model with the results of the operating solar neutrino experiments. We will see that this comparison leads to three different discrepancies between the calculations and the observations, which I will refer to as the three solar neutrino problems.

Figure 2 shows the measured and the calculated event rates in the five solar neutrino experiments (Homestake, GALLEX, SAGE, Kamiokande and Super-Kamiokande) for which quantitative results are available at the time of this writing. The figure reveals three discrepancies between the experimental results and the expectations based on the combined standard model. As we shall see, only the first of these discrepancies depends at all sensitively on predictions of the standard solar model.

Calculated versus observed chlorine rate

The first solar neutrino experiment to be performed was the chlorine radiochemical experiment, which detects electron-type neutrinos that are more energetic than 0.81 MeV. After more than 30 yr of the operation of this experiment, the measured event rate is 2.56 ± 0.23 SNU, which is a factor 3 less than is predicted by the most detailed theoretical calculations. Most of the predicted rate in the chlorine experiment is from the rare, high-energy ^{8}B neutrinos, although the ^{7}Be neutrinos are also expected to contribute significantly. According to standard model calculations, the pep neutrinos and the CNO neutrinos (for simplicity not discussed here) are expected to contribute less than 1 SNU to the total event rate.

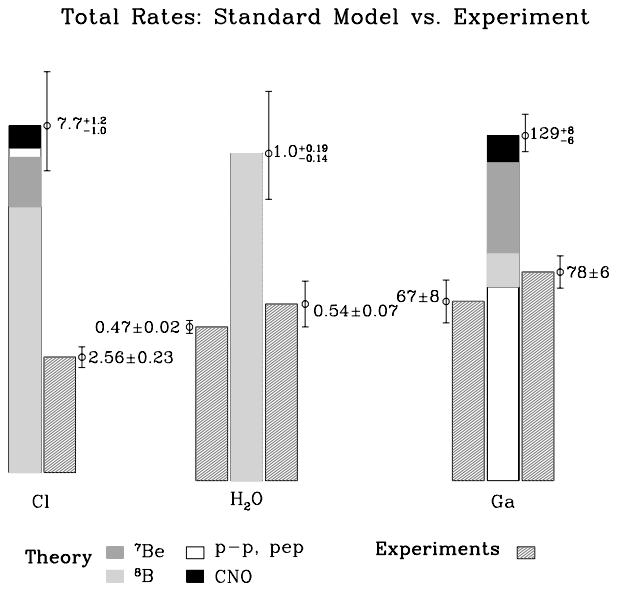

Figure 2. Comparison of measured rates and standard-model predictions for four solar neutrino experiments.

This discrepancy between the calculations and the observations for the chlorine experiment was, for more than two decades, the only solar neutrino problem. I shall refer to the chlorine disagreement as the 'first' solar neutrino problem. (It used to be called 'the' solar neutrino problem.)

Incompatibility of chlorine and water experiments

The second solar neutrino problem results from a comparison of the measured event rates in the chlorine experiment and in the Japanese pure-water experiments, Kamiokande and Super-Kamiokande. The water experiments detect higher-energy neutrinos, those with energies above 7.5 MeV (Kamiokande) or 6.5 MeV (Super-Kamiokande, so far), by neutrino–electron scattering: $\nu + e \longrightarrow \nu' + e'$. According to the standard solar model (see also table 1), ^{8}B beta decay is the only important source of these higher-energy neutrinos.

The Kamiokande and Super-Kamiokande experiments show that the observed neutrinos come from the Sun. The electrons that are scattered by the incoming neutrinos recoil predominantly in the direction of the Sun–Earth vector; the relativistic electrons are observed by the Cherenkov radiation they produce in the water detector.

In addition, the water experiments measure the energies of individual scattered electrons and therefore provide information about the energy spectrum of the incident solar neutrinos. The currently most popular parameters for neutrino oscillations predict only relatively small deviations from the spectrum expected with no oscillations. Indeed, Super-Kamiokande does observe a deviation that can be explained by neutrino oscillations but as of the time of this writing the statistical significance is not very high.

The event rate in the Kamiokande experiment is determined by the same high-energy ^{8}B neutrinos that are expected, on the basis of the combined standard model, to dominate the event rate in the chlorine experiment. I have shown elsewhere that solar physics changes the shape of the ^{8}B neutrino spectrum by less than 1 part in 10^5. Therefore, we can calculate the rate in the chlorine experiment that is produced by the ^{8}B neutrinos observed in the Super-Kamiokande experiment (6.5 MeV threshold energy). This partial (^{8}B) rate in the chlorine experiment is 2.78 ± 0.10 SNU, which exceeds by about one standard deviation the total observed chlorine rate from all neutrino sources, of 2.56 ± 0.23 SNU.

Comparing the rates of the Kamiokande and the chlorine experiments, one finds that the net contribution to the chlorine experiment from the pep, ^{7}Be and CNO neutrino sources is negative: -0.22 ± 0.10 SNU. The standard model calculated rate from pep, ^{7}Be and CNO neutrinos is 1.9 SNU.

The apparent incompatibility of the chlorine and the Kamiokande experiments is the 'second' solar neutrino problem. The inference that is often made from this comparison is that the energy spectrum of ^{8}B neutrinos is changed from the standard shape by physics not included in the simplest version of the standard electroweak model.

Gallium experiments: no room for ^{7}Be neutrinos

The results of the gallium experiments, GALLEX and SAGE, constitute the third solar neutrino problem. The average observed rate in these two experiments is 73 ± 5 SNU, which is essentially fully accounted for in the standard model by the theoretical rate of 72 SNU that is calculated to come from the basic p–p and pep neutrinos (with only a 1% uncertainty in the standard solar model p–p flux). The ^{8}B neutrinos, which are observed above 6.5 MeV in the Super-Kamiokande experiment, must also contribute to the gallium event rate. Using the standard shape for the spectrum of ^{8}B neutrinos and normalizing to the rate observed in Kamiokande, ^{8}B contributes another 6 SNU, unless something happens to the lower-energy neutrinos after they are created in the Sun. (The predicted contribution is 12 SNU on the basis of the standard model.) Given the measured rates in the gallium experiments, there is no room for the additional 34 ± 4 SNU that is expected from ^{7}Be neutrinos.

The seeming exclusion of everything but p–p neutrinos in the gallium experiments is the 'third' solar neutrino problem. This problem is essentially independent of the previously discussed solar neutrino problems, since it depends on the p–p neutrinos that are not observed in the other experiments and whose calculated flux is approximately model independent (if the general scheme of the p–p chain shown in table 1 is correct).

The missing ^{7}Be neutrinos cannot be explained away by any change in solar physics. The ^{8}B neutrinos that are observed in the Kamiokande experiment are produced in competition with the missing ^{7}Be neutrinos;

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

the competition is between reaction 6 and reaction 8 in table 1. Solar model explanations that reduce the predicted ^{7}Be flux reduce much more (too much) the predictions for the observed ^{8}B flux.

I conclude that either (1) at least three of the four operating solar neutrino experiments (the two gallium experiments plus either chlorine or Kamiokande) have yielded misleading results or (2) physics beyond the standard electroweak model is required to change the neutrino energy spectrum (or flavor content) after the neutrinos are produced in the center of the Sun.

What have we learned?

No solar-model solution has been found that explains the results of the five existing solar neutrino experiments. Many particle physics solutions have been proposed that can explain the existing data. In this section, I will summarize the main astronomical lessons that have been learned from the first 30 yr of solar neutrino research.

The chlorine solar neutrino experiment was proposed in 1964 as a practical test of solar model calculations. The only motivation presented in the theoretical and experimental papers was to use neutrinos 'to see into the interior of a star and thus verify directly the hypothesis of nuclear energy generation in stars'.

What have we learned by direct experiments about nuclear energy generation in stars? How does our 1964 understanding compare with the results of the solar neutrino experiments? Table 2 summarizes the six principal predictions that were made (or which were implicit in the theory) in 1964 and compares those predictions with the results of the four ongoing solar neutrino experiments.

The neutrinos were predicted to originate in the solar interior; the direction of origin of the neutrinos has been verified by detecting neutrino–electron scattering (as was also suggested in 1964) in the Kamiokande and Super-Kamiokande experiments.

The rates of the four operating experiments are in semiquantitative agreement with the predictions; the ratios of the observed to the predicted rates are 0.3 (chlorine), 0.5 (neutrino–electron scattering in water), and 0.6 (gallium, average). This agreement is better than any of us dared hope for in 1964, especially since the dominant neutrino flux (from ^{8}B beta decay) for the first two experiments depends on the central temperature of the Sun as approximately the 24th power of the central temperature.

The energy range of the dominant neutrinos was predicted to be from 0 MeV to 14 MeV, which is consistent with the observations from the Kamiokande and Super-Kamiokande experiments.

Standard models predict that the neutrino fluxes are constant in time except for a small seasonal variation. (The Kelvin–Helmholtz cooling time for the solar interior is $\sim 10^7$ yr.) The consensus view of the experimentalists is that there are no statistically significant variations in the available data. Small deviations from the constant flux prediction are predicted by some of the popular neutrino oscillation scenarios, but improved statistics are required to test these predictions.

Standard solar models predict that the Sun shines almost entirely via the p–p chain of nuclear fusion reactions, rather than the CNO reactions originally emphasized by Bethe. If CNO reactions were dominant, the event rates in solar neutrino experiments could be calculated precisely. These 'all-CNO' rates, as shown in table 2, differ from the observed rates by more than an order of magnitude. Finally, if we crudely characterize the rate of the ^{8}B neutrino emission by its approximate dependence on the central temperature of the solar model, then the central temperature of the solar model agrees with the value obtained from the experimental rates to an accuracy of $\sim$2% or better.

The pioneering solar neutrino experiments have shown directly that the Sun shines by nuclear fusion reactions, thus achieving the original goal proposed in 1964. Quantitative improvements in the tests shown in table 2 will occur with the next generation of experiments, which should also refine our knowledge of the physical properties of neutrinos. However, the most important qualitative result has been established: *neutrinos have been observed from the interior of the Sun in approximately the number and with the energies expected*.

In the more than three-decade long struggle to improve solar models in order to calculate more accurate solar neutrino fluxes, we have obtained a greater understanding of solar structure. The theoretical models have gradually been refined as improved input data, more accurate physical descriptions and more precise numerical techniques have been employed. Perhaps most importantly, the complementary field of helioseismology has been developed and now provides precise data that determine the sound velocity over most of the solar interior; these beautiful measurements are used to test and to refine the standard solar model. Further improvements in the solar model are desirable and important, but the quantitative agreement, typically better than 1 part in 1000, between the calculated eigenfrequencies of pressure modes and the measured (helioseismological) frequencies provides strong evidence for the basic correctness of the standard solar model.

What next?

In this section, I will summarize the goals of solar neutrino research, first in physics and then in astronomy, during the next decade or two.

Physics goals

The fundamental goal of physics research with solar neutrinos is to measure the energy spectrum and flavor content as a function of time of the solar neutrino flux. We want to know how many neutrinos reach the Earth with a given energy and with a given flavor (i.e. neutrino type: e, μ or τ), all as a function of time. Because of some exotic particle physics possibilities, we also want to

Table 2. Predictions versus observations: 1964 versus 1995.

Property	Predicted	Observed
Direction	From the Sun	OK
Rates	Measurable	~ Predicted rates (within factor of few)
Neutrino energy	0–15 MeV	<15 MeV
Time dependence	Constant (except seasonal)	OK
p–p not CNO	If CNO: Cl : 28 SNU	2.6 SNU
	Ga : 610 SNU	73 SNU
	H_2O : 0.0	0.44 standard model
Central temperature	16×10^6 K	$T(^8B)/T_{model} \gtrsim 0.98$

know whether the solar neutrino flux contains any anti-neutrinos.

The standard model predicts that the energy spectrum of neutrinos from any given neutrino source, e.g. from ^{8}B beta decay, will be the same to high accuracy as the energy spectrum inferred from terrestrial laboratory measurements. In the standard electroweak theory, only massless electron-type neutrinos are created in nuclear beta decay or nuclear fusion reactions. Standard electroweak theory predicts that the solar neutrinos produced by nuclear fusion reactions are all ν_e, not ν_μ or ν_τ. (According to MSW and vacuum oscillation theories, neutrinos created in nuclear beta decay or nuclear fusion reactions are linear combinations of different neutrino types and at least one neutrino type has a non-zero mass.) Finally, the total amount of thermal energy in the solar interior implies that the neutrino fluxes will be constant in time (for time scales less than 10^7 yr) except for the seasonal dependences caused by the Earth's orbital eccentricity. Any departure from these expectations will be a signal of physics beyond the standard electroweak model.

Physicists want to use solar neutrino experiments to measure, or to set stringent limits on, the elementary properties of neutrinos, especially their masses and mixing angles. It seems likely that we will make important progress toward this goal in the next decade.

Astronomy goals

The fundamental goal of solar neutrino astronomy is to determine the rates of different nuclear fusion reactions in the solar interior. Neutrino fluxes created by the different nuclear sources are the signatures of the fusion reactions. We must know what happens to the neutrinos after they are created in order to infer the created neutrino energy spectrum from the measured neutrino energy spectrum.

Progress in solar neutrino astronomy is held hostage to progress in particle physics. As discussed in the previous subsection, it seems likely that we will learn enough about the particle physics in the next decade to permit accurate inferences about the rates of neutrino creation in the Sun from the observed rates of neutrino arrival at the Earth. The discussion in this subsection presumes that the required progress in understanding the properties of the neutrino will be achieved.

Completing hydrogen fusion Table 1 shows that the two principal ways of completing nuclear fusion in the sun are reactions 4 and 5, the so-called ^{3}He–^{3}He and ^{3}He–^{4}He reactions. Because of the slightly smaller reduced mass that exists for the ^{3}He–^{3}He reaction, Coulomb barrier penetration favors this reaction over the ^{3}He–^{4}He reaction at lower temperatures. According to the standard solar model, the ^{3}He–^{4}He reaction is dominant in the innermost region of the Sun (where it is 1.5 times faster than the ^{3}He–^{3}He reaction), but overall occurs in only ~15% of the fusion terminations that are described by equation (1). That is, in the most detailed solar models, the ^{3}He–^{3}He reaction is on average more than 6 times faster in completing the nuclear fusion of protons into α-particles than the competing ^{3}He–^{4}He reaction.

Is this prediction of the standard solar model correct? A determination of the p–p and ^{7}Be neutrino fluxes (corrected for what non-standard particle physics has done to them after they were created in the Sun) can answer this important question. The average ratio of the total number of ^{3}He–^{4}He reactions per unit time in the Sun to the total number of ^{3}He–^{3}He reactions per unit time in the Sun is

$$\frac{\langle {}^3\text{He}\text{–}{}^4\text{He}\rangle}{\langle {}^3\text{He}\text{–}{}^3\text{He}\rangle} = \frac{2\phi(^7\text{Be})}{\phi(\text{p–p}) - \phi(^7\text{Be})} \qquad (6)$$

where ϕ(p–p) and $\phi(^7$Be) are, respectively, the fluxes from the p–p and ^{7}Be neutrinos.

Equation (6) is the most precisely testable prediction that I know of that follows directly from the theory of stellar energy generation. The known theoretical uncertainties in the calculation of the average solar ratio of ^{3}He–^{4}He to ^{3}He–^{3}He reactions is 9%.

The ^{8}B neutrino flux The flux of neutrinos from ^{8}B beta decay in the Sun (see reaction 9 of table 1) is, in principle, the simplest solar neutrino flux to measure. The higher energies of the ^{8}B neutrinos make them easiest to detect. For this reason, the Kamiokande, Super-Kamiokande and SNO neutrino experiments will all concentrate on the ^{8}B neutrinos.

However, one must determine the total flux of ^{8}B neutrinos, including the more difficult to detect μ or τ neutrinos that may have been produced by

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

neutrino oscillations from the originally created electron-type neutrinos. The total number of neutrinos of all types will be measured directly in the SNO experiment via the neutral-current disintegration of deuterium and, less directly, via electron–neutrino scattering in Super-Kamiokande. (This statement presumes there are no sterile neutrinos, i.e. neutrinos that do not interact with matter.)

The magnitude of the ^{8}B flux (all neutrino flavors), which is a sensitive probe of the temperature of the solar interior, varies approximately as $T_{\rm central}^{24}$. Therefore, it is important to determine experimentally the total ^{8}B solar neutrino flux.

The temperature profile of the solar interior A precision test of the theory of stellar structure and stellar evolution can be performed by measuring the average difference in energy between the neutrino line produced by ^{7}Be electron capture in the solar interior and the corresponding neutrino line produced in a terrestrial laboratory. This energy shift is calculated to be 1.29 keV. The energy shift is approximately equal to the average temperature of the solar core, computed by integrating the temperature over the interior of a standard solar model with a weighting factor equal to the locally produced ^{7}Be neutrino emission. The total range of values for the shift, calculated for a number of modern solar models (going back to 1982), is 0.06 keV.

A measurement of the energy shift is equivalent to a measurement of the central temperature distribution of the Sun.

The calculated energy profile of the ^{7}Be line contains, analogous to line-broadening in classical (photon) astronomy, information about the distribution of solar interior temperatures. The theoretical shape of the ^{7}Be neutrino line is asymmetric: on the low-energy side, the line shape is Gaussian with a half-width at half-maximum of 0.6 keV, and, on the high-energy side, the line shape is exponential, with a half-width at half-maximum of 1.1 keV.

The calculated shape of the ^{7}Be neutrino line is not affected significantly by vacuum neutrino oscillations, the MSW effect or other frequently discussed weak interaction solutions to the solar neutrino problems. This is a key result: it implies that the astronomical information contained in the line shift and in the line profile is not dependent on further progress in neutrino physics.

Detectors are available that have the resolution to measure the line shift. Unfortunately, their current sizes are too small to permit a full-scale solar neutrino experiment. However, proposals have been made in the literature for developing detectors that are sufficiently large to be able to measure well the average shift in energy of the solar neutrino line.

More complete models of the Sun The accuracy of the physical description that is currently achieved with one-dimensional (spherically symmetric) models of the Sun that include diffusion is sufficient to permit excellent quantitative agreement with the measured p-mode oscillation frequencies. Numerical experiments and theoretical arguments also suggest that further improvements are unlikely to affect significantly the calculated neutrino fluxes.

Nevertheless, current models of the Sun are incomplete. They are spherically symmetric and do not take account of the two-dimensional (or three-dimensional) nature of solar structure. They do not contain a self-consistent dynamical treatment of the effects of rotation, of magnetic fields, of mass loss or of other possible effects that may violate the currently used approximations of spherical symmetry and quasi-static evolution. We know observationally that the Sun (at least near its surface) contains magnetic fields, that it is losing mass, and that it departs from spherical symmetry by $\sim$1 part in 10^5.

There are both analytic and calculational challenges in including these complicated processes in a more complete physical description in the next generation of solar models. New self-consistent methods of calculating solar models (and stellar models) must be developed, and then the appropriate numerical techniques must be worked out, tested and applied.

The goal of developing a more complete solar model is a challenge for the next decade and beyond. Fortunately, it is a challenge that could lead to important progress since computing power is much greater than it was in the past and there is an abundance of precision data with which to make detailed comparisons.

Summary

The first 30 yr of solar neutrino research have verified experimentally the fundamental predictions of nuclear energy generation in stars. The next 10 or 20 yr of research will, I think, concentrate on using solar neutrinos to learn more about weak interaction physics. As the weak interaction questions are being resolved, it will be possible to carry out progressively more accurate tests of the theory of nuclear energy generation and of stellar structure.

In retrospect, the history of solar neutrino research seems ironic. It began with an effort to use neutrinos, whose properties were assumed to be well known, to study the interior of the nearest star. The project was an unconventional application of microscopic physics that was designed to carry out a unique investigation of a massive, macroscopic body, the Sun. It now appears likely that a large community of physicists, chemists, astrophysicists, astronomers and engineers working together may have stumbled across the first observed manifestation of physics beyond the standard electroweak model.

We may have been incredibly lucky.

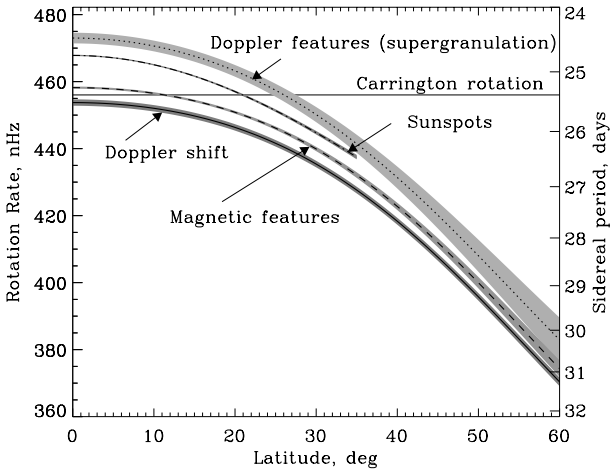

Figure 1. Rotation rate, $\Omega/2\pi$, and period of various tracers on the Sun's surface: recurrent (old) sunspots (dashed curve), magnetic features (dot–dash), and Doppler features (dots). The rotation rate and period determined spectroscopically through the Doppler shift are shown by the full curve. The shaded areas show the 1σ error estimates.

Solar Interior: Rotation

The Sun rotates differentially, i.e. the solar rotation rate varies with both latitude and radius. The differential rotation is particularly prominent in the convection zone where equatorial zones rotate almost 30% faster than near-polar regions. There are also strong variations of the rotation rate with radius near the surface and at the bottom of the convection zone (rotational shear layers). In contrast to the convection zone, the radiative zone rotates almost uniformly, although the rotation rate of the inner solar core has not been determined reliably. The mechanisms of the differential rotation, which are probably due to the interaction between convection and rotation, are not fully understood. The differential rotation is believed to play a major role in the dynamo mechanism of solar activity. It also affects the internal structure of the Sun because of rotational instabilities related to rotational shear layers. Knowledge of the internal rotation (in particular, whether the inner core rotates rapidly) is important for determining the quadrupole gravitational moment of the Sun and testing Einstein's theory of relativity (SOLAR INTERIOR: SOLAR DIAMETER, OBLATENESS, AND TEMPERATURE).

Measurements of solar rotation

It has been known since the first observations of solar rotation around 1610 by GALILEO GALILEI, Johannes FABRICIUS and Christoph SCHEINER that the solar equator rotates faster than the regions closer to the poles (latitudinal differential rotation). However, the accurate determination of the differential rotation on the solar surface and in the deep interior is still one of the major problems of solar physics. A unique tool for determining the rotation of the Sun's interior is provided by helioseismology.

Differential rotation

There are two basic approaches for measuring the surface rotation: spectroscopic and tracer motion. The spectroscopic method is based on measuring the Doppler line shift. It provides the angular velocity in those layers of the solar atmosphere where the spectral lines chosen for the measurements are formed. In principle, by observing the spectroscopic shift in several lines it is possible to determine the variation of solar rotation with height in the solar atmosphere because different spectral lines are formed in different layers of the atmosphere. Such measurements of the radial variation of the rotation in the surface layers are not particularly accurate, because of the significant noise caused by large-scale convective motions—supergranulation. Nevertheless, these measurements have provided evidence that the lower layers of the solar atmosphere, and thus presumably the subsurface layers, rotate faster. This was later confirmed by helioseismology.

The tracer measurements are carried out either by tracking the rotation rate of individual resolved features on the surface (such as sunspots, active regions, supergranular cells etc) as they pass across the disk, or by cross-correlating magnetograms and Dopplergrams obtained at different times.

Representations of the surface differential rotation

Angular velocity Ω of the surface differential rotation as a function of co-latitude θ is usually represented in a parametric form. Historically, it was given in terms of trigonometric functions:

$$\Omega(\theta) = A + B\cos^2\theta + C\cos^4\theta \qquad (1)$$

where the coefficient A gives the equatorial rotation rate ($\theta = 90^\circ$), and coefficients B and C give the differential rotation. However, the basis functions in this expansion are not orthogonal. This results in correlated errors ('cross-talk') among the coefficients. Therefore, more recently a presentation in terms of orthogonal polynomials has been used:

$$\Omega(\theta) = \bar{A} + \bar{B}T_2^1(\theta) + \bar{C}T_4^1(\theta) \qquad (2)$$

where $T_{2k}^1(\theta) \equiv a_k P_{2k+1}^1(\theta)/\sin\theta$, $a_k = k!2^k/(2k+1)!!$ and $P_\lambda^1(\theta)$ are the associate Legendre functions of order 1 and degree λ. For the first two terms, $T_2^1(\theta) = 5\cos^2\theta - 1$ and $T_4^1(\theta) = 21\cos^4\theta - 14\cos^2\theta + 1, a_0 = 1, a_1 = 2/3, a_2 = 8/15$. Coefficients $\bar{A}$, $\bar{B}$ and $\bar{C}$ are linear combinations of A, B and C of equation (1):

$$\bar{A} = A + \tfrac{1}{5}B + \tfrac{3}{35}C \qquad \bar{B} = \tfrac{1}{5}B + \tfrac{2}{15}C \qquad \bar{C} = \tfrac{1}{21}C.$$

The equatorial angular velocity in this formulation is given by $\bar{A} - \bar{B} + \bar{C}$. The coefficients of the orthogonal representation (equation (2)) are usually obtained with higher accuracy that the coefficients of equation (1).

The surface angular velocity is usually measured in deg day^{-1} or μrad s^{-1}. However, for internal rotation obtained by helioseismology the typical measure

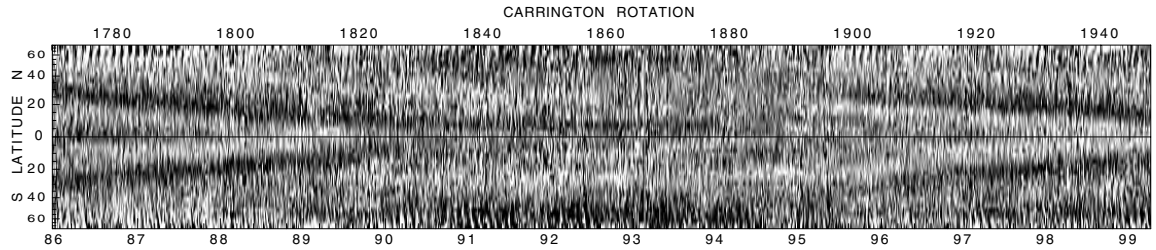

Figure 2. Migrating zonal flows ('torsional oscillations') in 1986–99, determined from the Mt Wilson Observatory data. The vertical scale is latitude in degrees, the lower horizontal axis shows time in years starting from 1986, and the upper scale shows the corresponding Carrington rotation numbers. The dark areas correspond to a rotational velocity 7.5 m s^{-1} faster than the average velocity, and the light area shows rotation 7.5 m s^{-1} slower than the average (Ulrich 1998).

is the rotation rate, $\Omega/2\pi$, expressed in nanohertz (nHz). Therefore, we shall use this measure in this article. The rotation rate can converted in the angular velocity units using the following relations: 1 nHz $= 6.283 \times 10^{-3}$ μrad $s^{-1} = 0.031$ deg day^{-1}. The typical rotation rate at the solar equator is about 460 nHz (2.89 μrad s^{-1} or 14.31 deg day^{-1}), and corresponds to a linear velocity of 2012 m s^{-1}.

Measurements of the surface rotation

The coefficients of the sidereal rotation rate of different features on the solar surface are shown in table 1 and figure 1 (Snodgrass 1992). The surface features (tracers) related to magnetic field structures rotate faster than the solar plasma, rotation of which is measured from the Doppler shift of spectral lines. The magnetic structures are likely to be anchored in the solar interior. Therefore, the faster rotation of these structures probably can be related to higher angular velocity of the interior. The averaged period of rotation of sunspots is close to the 'Carrington period', 25.38 days (the corresponding synodic period is 27.275 days). The Carrington period corresponds to the differential rotation of recurrent (i.e. old) sunspots at approximately 20° latitude and is often used as a reference. The surface rotational velocity at this latitude is approximately 1.9×10^3 m s^{-1}. It is found that the rotation rate of individual sunspots may vary depending their size, age and relative position to other sunspots of the same group.

Observations of solar rotation have also revealed temporal variations related to the 11 yr activity cycle. These include an increase in the equatorial rotation rate at solar minimum and a migrating pattern of zonal flow bands, known as 'torsional oscillations' (figure 2). The bands start at high latitudes near solar maximum and approach the solar equator at solar minimum.

Helioseismic measurements

Helioseismology provides a picture of rotation inside the Sun as a function of both depth and latitude. The helioseismic measurements are based on the frequency shift of resonant solar oscillations (modes) due to rotation. The modes which propagate in the direction of solar rotation have higher frequencies than the modes with the same resonant properties propagating in the opposite direction. This effect called 'rotational frequency splitting' is somewhat analogous to the Zeeman or Stark splitting of energy levels in atoms. The amount of splitting depends on the rotation rate in the mode resonant cavity and their azimuthal order (HELIOSEISMIC OBSERVATIONS, HELIOSEISMOLOGY: THEORY).

Rotational frequency splitting

The mode frequencies, ν_{nlm}, are characterized by three 'quantum numbers': radial order n which is essentially the number of radial nodes in the mode eigenfunction and the angular degree l and azimuthal order m ($-m \leq l \leq m$) which come from the spherical harmonic part of the eigenfunctions, $\Xi_n(r)Y_l^m(\theta, \phi)$. The modes with $m \neq 0$ represent azimuthally propagating waves. The modes with $m > 0$ propagate in the direction of solar rotation and, thus, have higher frequencies in the inertial

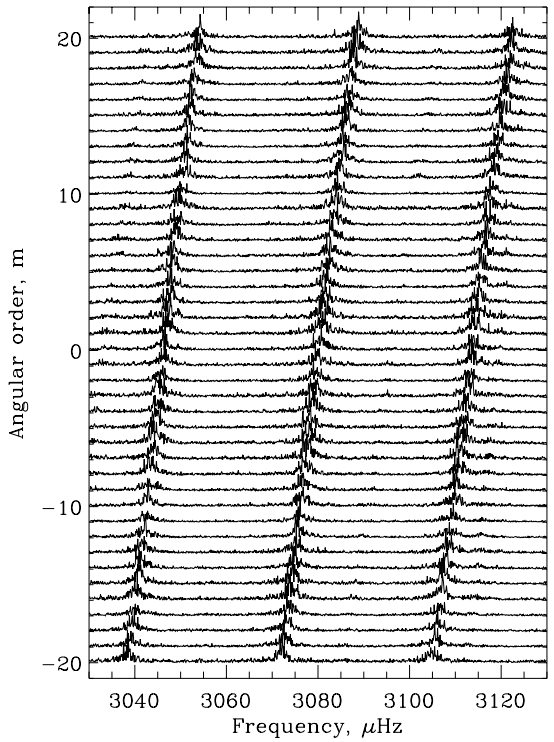

Figure 3. Typical power spectra of solar oscillation data from the MDI instrument on SOHO. Each horizontal curve shows three lines of the power spectrum for different azimuthal order m with radial order $n = 15$ and angular degree $l = 19$, 20, and 21 (from left to right). The slope of the modal lines is due to the rotational frequency shift: prograde modes with positive m have higher frequencies than retrograde modes with negative m.

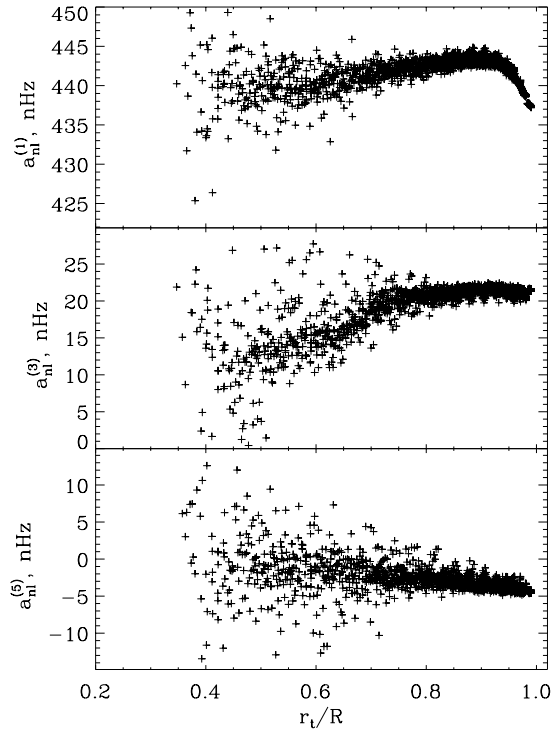

Figure 4. Rotational splitting coefficients obtained from a 144 day observing run from SOHO/MDI. The coefficients are plotted as a function of r_t, the radius of the mode turning point, which is determined for each mode from the relation: $r_t/c(r_t) = L/2\pi\nu_{nl0}$, where $c(r)$ is the sound speed.

frame than the modes with $m < 0$ which propagate in opposite direction. As a result the modes with fixed n and l are split in frequency: $\Delta\nu_{nlm} = \nu_{nlm} - \nu_{nl0}$. Thus, the internal rotation is inferred from splitting of normal mode frequencies with respect to the azimuthal order, m.

An example of the frequency splitting is shown in figure 3, in which the horizontal curves are oscillation power spectra for $m = -20, \ldots, 20$ of modes with $n = 15$ and $l = 19$, 20 and 21. The slope formed by the modal peaks, $\Delta\nu_{nlm}/\Delta m$, is approximately the solar synodic rotation rate 0.43 μHz (or 430 nHz).

The frequency splitting is proportional to m and the internal angular velocity $\Omega(r, \theta)$ averaged over radius r and colatitude θ with splitting kernels $K_{nlm}(r, \theta)$:

$$\Delta\nu_{nlm} = m \int_0^R \int_0^\pi K_{nlm}(r, \theta)\Omega(r, \theta)\, \mathrm{d}\theta\, \mathrm{d}r$$

where R is the solar radius. The kernels K_{nlm} are calculated from mode eigenfunctions.

The determination of $\Omega(r, \theta)$ from a set of observed $\Delta\nu_{nlm}$ represents a helioseismic inverse problem. This problem is solved by a regularized least-squares method or by estimating optimally localized averages $\bar{\Omega}(r_0, \theta_0)$ from a linear combination of the data:

$$\bar{\Omega}(r_0, \theta_0) = \sum_{nlm} c_{nlm}(r_0, \theta_0)\Delta\nu_{nlm}$$

where the coefficients c_{nlm} are chosen to localize the corresponding averaging kernel $A(r, r_0) \equiv \sum_{nlm} c_{nlm}(r_0, \theta_0)K_{nlm}(r, \theta)$ at the target position (r_0, θ_0). When the localization attempt is successful the optimally localized kernels resemble a Gaussian, and $\bar{\Omega}(r_0, \theta_0)$ provides a good estimate of the angular velocity.

The measurements of $\Delta\nu_{nlm}$ are often noisy. Therefore, it is useful to determine the frequency splitting in terms of Legendre polynomials in m/L, where $L = [l(l+1)]^{1/2}$:

$$\Delta\nu_{nlm} = L \sum_{i=1}^{N} a_{nl}^{(i)} P_i\left(\frac{m}{L}\right)$$

where N is typically 5–36. (In some recent measurements the Legendre polynomials are replaced with orthogonal polynomials in m/L.) The odd terms in this equation represent the rotational splitting; the even terms are due to asphericity of the solar structure.

If the internal angular velocity is represented in the form of equation (2) with the coefficients depending on radius r,

$$\Omega(r, \theta) = \bar{A}(r) + \bar{B}(r)T_2^1(\theta) + \bar{C}(r)T_4^1(\theta)$$

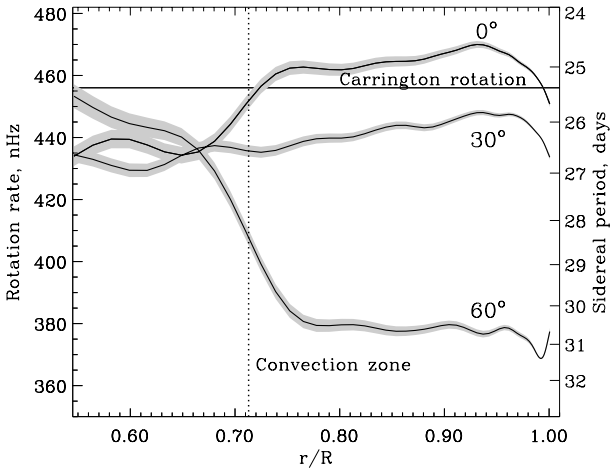

Figure 5. Solar rotation rate inferred from 144 day series of MDI medium-*l* data as a function of radius at three latitudes, 0°, 30° and 60°. The formal errors are indicated by the shaded regions. The vertical straight line shows the lower boundary of the convection zone (Schou *et al* 1998).

then each of the coefficients in this form is primarily determined from the individual $a_{nl}^{(i)}$ coefficients:

$$a_{nl}^{(1)} = \int_0^R K_{nl}^{(1)}(r)\bar{A}(r)\,\mathrm{d}r$$
$$a_{nl}^{(3)} = -\int_0^R K_{nl}^{(3)}(r)\bar{B}(r)\,\mathrm{d}r$$
$$a_{nl}^{(5)} = \int_0^R K_{nl}^{(5)}(r)\bar{C}(r)\,\mathrm{d}r. \qquad (3)$$

The radial functions $\bar{A}(r)$, $\bar{B}(r)$ and $\bar{C}(r)$ can be determined by solving the one-dimensional integral equations (3).

For acoustic (p) modes the seismic kernels $K_{nl}^{(i)}(r)$ are significant mainly inside the mode propagation region, (r_t, R), where r_t is the radius of the inner turning point of acoustic modes and R is the solar radius. Therefore, it is useful to plot the a coefficients as a function of r_t (figure 4). Each point in this plot represent an average of $\bar{A}(r)$, $\bar{B}(r)$ and $\bar{C}(r)$ in the interval (r_t, R). The first coefficient, $a^{(1)}$, which corresponds to the spherically symmetric component of the angular velocity, $\bar{A}(r)$, shows a steep decrease with r_t near the surface. This corresponds to the increase of the angular velocity with depth in the subsurface layers.

The coefficient $a^{(3)}$, which determines the prime component of the latitudinal differential rotation, shows a decrease below $0.7R$, the lower boundary of the convection zone. Therefore, one may expect a decrease of the differential rotation in the radiative zone. In this way, investigating seismic data versus the radius of the mode turning points helps us to make qualitative inferences without solving the inverse problem.

Results of helioseismic measurements

The rotation rate inferred by inversion as a function of radius at the equator and at 30° and 60° latitude is shown in figure 5. It shows that the latitudinal differential rotation extends through the convection zone and is sharply reduced in the radiative zone.

The layer of transition from the differential rotation in the convection zone to almost uniform rotation in the radiative zone is characterized by a strong radial gradient of the angular velocity at low and high latitudes. This is probably the place where the global magnetic field of the Sun is generated in the course of the 11 yr cycle. The part of the transition layer which is located in the transition layer is called the 'tachocline'. Because the internal rotation matches the Carrington rotation only in low-latitude zones, it is likely the magnetic field which constitutes sunspots is generated at low latitudes. Most of the transition layer is located beneath the lower boundary of adiabatic convection (shown in figure 5 by the vertical dashed line) which is located at 0.713 solar radii. The estimates of the width of the transition layer range from 0.05 to 0.1 solar radii.

Another region with a strong radial gradient of the angular velocity is located near the upper boundary of the convection zone above 0.95 solar radii.

Contour lines of the rotation rate in a cross-section of the interior are shown in figure 6. The lines of constant angular velocity are quite complicated and follow neither radial nor vertical (cylindrical) lines as predicted by models of the differential rotation.

Rotation in the central and near-polar regions (shaded areas) has not been determined reliably. However, the current helioseismic data are consistent with the assumption that the central core rotates with the same rate as the outer part of the radiative zone, which is approximately 440 nHz (corresponding period 26.3 days).

The data also show that the rotation rate in the near-polar region of the upper convection zone is substantially (about 5%) lower than the rate estimated from the three-term formula (equation (1) or (2)) (figure 7). There is an indication that the polar rotation varies with the solar cycle.

The results in figure 7 also show variations of the rotation rate of ≈0.5% (2 nHz), or variations in the rotational velocity of 10 m s^{-1}, at low and mid-latitudes. These variations correspond to the migrating zonal flows ('torsional oscillations') associated with the solar activity. These flows extend to, at least, 5% of the solar radius (35 Mm) in depth.

North–south asymmetry

The observation of rotation of sunspots reveals the asymmetry in the differential rotation between the northern and southern hemispheres. The asymmetry correlates with the magnetic activity—the hemisphere with lower activity (fewer active regions) rotates faster than that with higher activity. The difference in the average rotation rate may reach 0.5% (10 m s^{-1}).

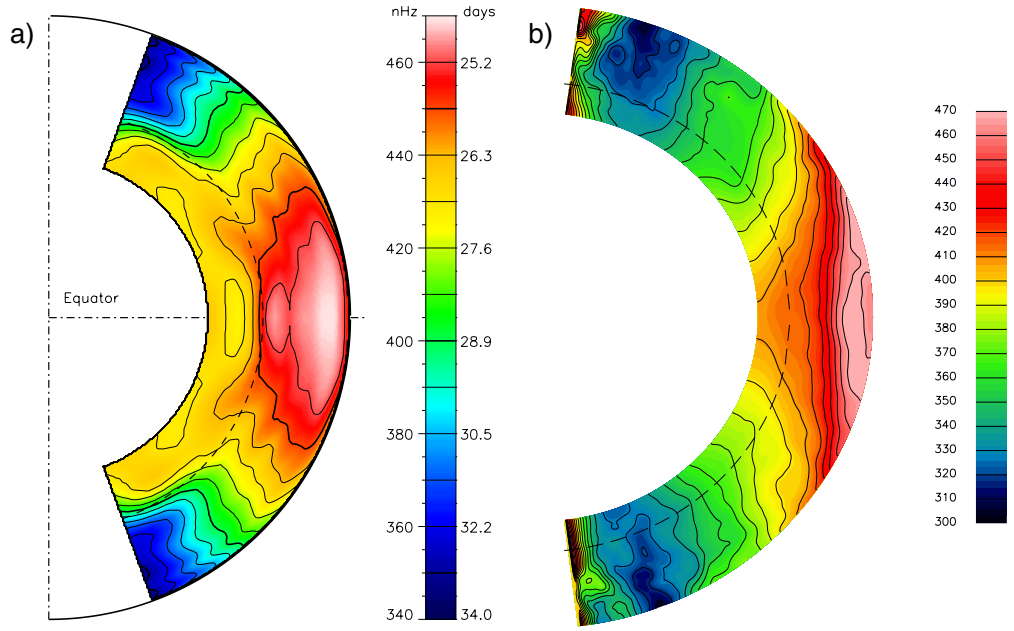

Figure 6. (*a*) Angular velocity profile $\Omega(r, \theta)$ as deduced from helioseismology, using the GONG data. (*b*) Time-averaged angular velocity profile obtained by a 3D simulation. The dashed lines indicate the lower boundary of the convection zone (Elliott *et al* 1998). **This figure is reproduced as Color Plate 55.**

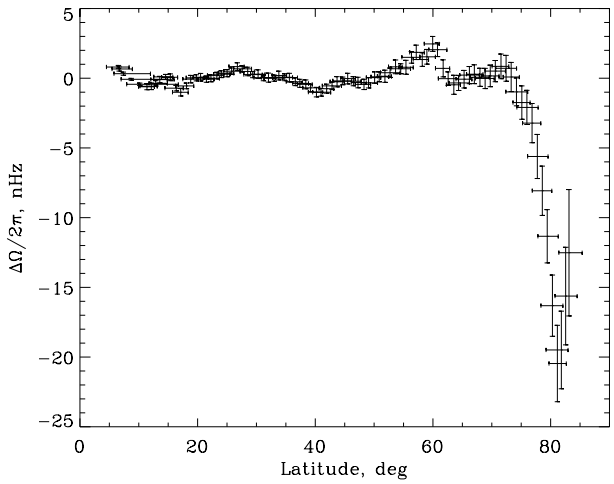

Figure 7. The deviation of the solar rotation rate from the three-term law (equation (1)) in the upper 4% of the convection zone. The horizontal bars indicated the half-width at half-maximum to the left and right of the peak of the localized averaging kernels, $A(r, r_0)$. The vertical bars indicate the standard error estimate (Birch and Kosovichev 1998).

The rotational frequency splitting is not sensitive to the asymmetrical component of rotation to first order. However, the north–south asymmetry of the internal rotation can be studied by methods of local helioseismology, e.g. ring-diagram and time–distance techniques (SOLAR INTERIOR: LOCAL HELIOSEISMOLOGY).

Theories of solar rotation

Evolution of solar rotation

The Sun rotates more slowly, by a factor of 50, than early main sequence stars. This suggests that the Sun initially rotated much faster and lost most of its angular momentum over its lifetime. The angular momentum of the Sun is believed to be lost as a result of 'magnetic braking' through the magnetized solar wind.

The magnetic braking is mainly applied to the surface layers of the Sun. However, it also slows down the interior because the deep layers of the Sun are coupled with the surface because of convective flows and internal magnetic field. In fact, the convection zone reacts to the external torque almost like a solid body because the angular momentum transport provided by turbulent friction is very efficient.

In the radiative zone the angular momentum transport is much less efficient. It primarily depends on the diffusion transport coefficient. This coefficient may be increased by various instabilities due to strong shearing motions or excitation of internal gravity waves in the convective overshoot layer or by instability arising from the accumulation of the ^{3}He at the outer boundary of the energy-generating core. The internal magnetic field provides probably the most efficient mechanism of angular momentum transport. Even a very weak magnetic field ($\simeq 10^{-6}$ G) is sufficient to slow down the solar core.

The theories of the evolution of solar rotation based on these mechanisms predicted that the central core might still rotate much faster than the surface. However, the

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

recent helioseismic data have provided strong evidence that the whole radiative zone rotates almost uniformly. Which of the mechanisms of angular momentum transport provide most of the braking is not yet understood.

Mechanisms of the latitudinal differential rotation

The angular momentum transport which causes the differential rotation of the convection zone results from thermal stresses and the anisotropic Reynolds stresses, $Q_{ij} = \langle u_i u_j \rangle$, where u_i and u_j are components of the convective velocity and the brackets mean an average over longitude ϕ. The anisotropy arises from the distortion of convection motions by the Coriolis force and other effects of rotation such as the meridional circulation.

The evolution of the angular momentum in the convection zone is described by non-linear Navier–Stokes equations. The coupling between the turbulent solar convection and rotation can be modeled in the 'mean-field' approximation by averaging over an ensemble of convective elements or by solving the equations numerically on a high-resolution spatial grid. Both approaches are still far from the real situation. The mean-field theory employs various approximations and assumptions for the mean anisotropic properties of convection, whereas the numerical models do not provide sufficient spatial resolution to model the fully developed turbulent convection accurately.

The basic mechanisms of the differential rotation can be understood from the conservation of the angular momentum in the convection zone (for more details see Stix 1989). Consider the velocity field, $\boldsymbol{v}$, in the convection zone as a superposition of the mean rotational velocity, $\langle v_\phi \rangle$, a meridional circulation, $\boldsymbol{v}_m = (\langle v_r \rangle, \langle v_\theta \rangle)$, and the convective velocity, $\boldsymbol{u}$:

$$\boldsymbol{v} = \langle \boldsymbol{v} \rangle + \boldsymbol{u}$$

From the azimuthal component of the equation of conservation of momentum,

$$\frac{\partial \boldsymbol{v}}{\partial t} + \boldsymbol{v} \cdot \nabla \boldsymbol{v} = -\frac{1}{\rho} \nabla P - \nabla \Phi$$

where ρ is the density, P is the pressure and Φ is the gravitational potential, and the conservation of mass,

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \boldsymbol{v}) = 0$$

we obtain the equation of the conservation of the angular momentum:

$$\frac{\partial}{\partial t} \left(\rho s^2 \Omega \right) + \nabla \cdot (\rho s^2 \Omega \boldsymbol{v}_m + \rho s \langle u_\phi \boldsymbol{u} \rangle) = 0 \qquad (4)$$

where $s = r \sin\theta$, and $\Omega = \langle v_\phi \rangle / s$. (Fluctuations of density which may also be important are not taken into account in equation (4).) This equation shows that the density of angular momentum, $\rho s^2 \Omega$, changes either because angular momentum is transported by the meridional circulation, $\boldsymbol{v}_m$, or because of the Reynolds stresses, $\langle u_\phi \boldsymbol{u} \rangle$. These two processes play important roles in the mechanism of the differential rotation, and, therefore, it is very important to study them. The meridional circulation and convective flows are studied by measuring the Doppler velocity of the solar plasma on the surface and inside the convection zone by time–distance helioseismology.

The numerical simulations have been able to reproduce the differential rotation qualitatively (figure 6(*b*)). However, there are significant differences. The simulations provide an angular velocity profile with the contour lines parallel to the rotation axis in the plot, meaning that the angular velocity is constant on cylindrical shells, whereas the observations reveal a more complicated profile. The 'cylindrical' distribution of the angular momentum is attributed to large-scale convective cells oriented north–south, so-called 'banana cells'. This type of convection results from the effect of the Coriolis force. Evidently, some other important physical processes are missing in the simulations. Perhaps the small-scale turbulent convection which is not resolved in the current simulations transports angular momentum quite differently, yielding other classes of mean flows and rotation profile.

The future efforts in our understanding of solar rotation will be focused on the precise determination of the rotation rate of the solar core, tachocline, near-polar regions and the upper convective boundary layer. It is very important to study variations of the solar rotation, both temporal and spatial, which are associated with the solar cycle, and, in particular, the variations in the tachocline and zonal flows ('torsional oscillations') because these studies will help us to understand the mechanism of solar activity.

Solar Interior: Solar Diameter, Oblateness and Temperature

The visible edge of the Sun is called the LIMB and is almost circular, but very small deviations from a spherical Sun are measurable. The largest deviation is a 'flattening' of the polar radius in comparison to the equatorial solar radius. The Sun's surface temperature is also not spherically symmetric but has a tiny asphericity in the form of a latitudinal temperature variation. The radius, shape and surface temperature may also change on SOLAR CYCLE (yearly) time scales and the measurement of these properties yields important clues about the Sun's interior, and the physical origins of the 11-year solar cycle.

Solar shape and temperature measurements

The limb of the Sun is not a sharply defined edge but declines in brightness smoothly as we measure from the solar disk to off of the limb. This limb brightness profile changes most rapidly within about an arcsecond of the edge, or visible photosphere of the Sun. Here the effects of the Earth's atmospheric blurring, and magnetic features in the Sun's photosphere and the higher solar atmosphere (like SUNSPOTS or FACULAE), tend to cause the limb profile to change with time and limb position. Real changes in the brightness or temperature of the photosphere will also affect the apparent limb profile. These effects make it difficult to measure the true angular position of the limb of the Sun against the sky, since variations in the form of the limb profile can be confused with limb position changes (see SOLAR PHOTOSPHERE: CENTER-TO-LIMB VARIATION). In general, solar shape and temperature variations are difficult to disentangle and accurate shape measurements must often depend on a simultaneous study of the Sun's brightness or temperature.

Measurements of the shape of the Sun, and in particular the solar oblateness (which can be expressed as the relative difference between the equatorial and polar diameters), have been published and debated for nearly a century. Interest in the solar oblateness over the last 35 years was rekindled by measurements from Princeton which suggested that general relativity may be seriously 'incomplete'. Subsequent data did not confirm these results, although the ensuing experimental activity has generated a better understanding of the SOLAR INTERIOR and atmosphere. Figure 1 shows oblateness measurements since the mid-1960s. The most recent observations have the smallest error bars and were obtained from space, above the blurring effect of the atmosphere. The dotted line, which the measurements seem to converge toward, describes the approximate 'flattening' or oblateness expected due to the nominal solar surface rotation rate. Although the rotational flattening of the Sun amounts to an equatorial–polar diameter difference of only about 12 km, it seems to be reliably observed in the modern experiments and if it does vary with time, the temporal changes are very small

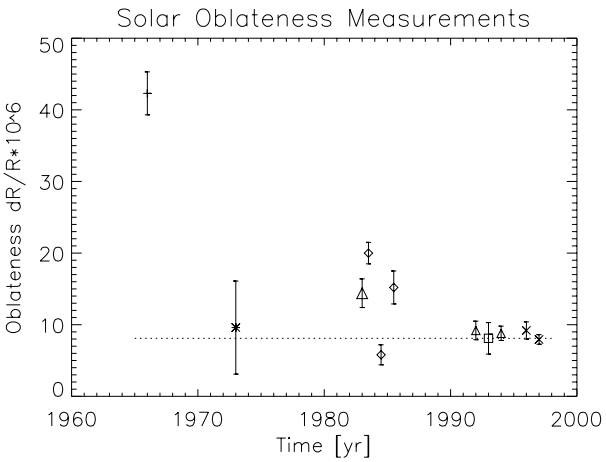

Figure 1. Recent measurements of the solar oblateness (10^6 times the fractional difference between equatorial and polar solar radii) are plotted versus time. The dotted line shows the expected solar flattening due to the nominal surface rotation rate.

(corresponding to less than about 1 km in the radius difference).

More complicated departures from a spherical limb shape have also been observed. Beyond the oblateness the next largest equator-symmetric departure from circularity is called the hexadecapole shape term and resembles a four-leaf clover pattern. The solar hexadecapole shape implies a solar diameter which is about 2 km smaller at mid-latitudes than near the equator or poles.

Limb shape measurements also reveal that the Sun's surface temperature varies with latitude and with the 11-year solar cycle by as much as a few kelvin. The poles and equator are always hotter than solar mid-latitudes by 1–2 K while the low-latitude regions, where sunspots and faculae appear on the surface, vary in brightness temperature throughout the 11-year solar cycle, but are usually a few degrees hotter than the mid-latitude photosphere. It is possible that the variability of the Sun's surface temperature has been mistaken as a variable solar diameter and oblateness in some solar size and shape measurements. This may help to explain the large variations in the early data points in figure 1.

Solar diameter measurements

Archival records of solar diameter measurements extend back to the mid-seventeenth century. By using the Earth's rotation to transit a solar image created by a long focal length telescope objective, the solar diameter could be deduced subject to the accuracy and repeatability of an observer's definition of the solar limb, and instrumental, timing and atmospheric distortion errors. Other historical diameter measurements have been inferred by timing solar eclipses, and by timing transits of Mercury across the solar disk. Although the many observations are not entirely consistent, there is no evidence that the Sun's diameter has changed by more than 2″ over the last

350 years. Modern optical measurements yield a solar diameter of 1919.36 ± 0.02 and imply that solar cycle (yearly) variations in the diameter are less than a few tenths of an arcsecond. The intercomparison of different diameter determinations is difficult because the solar limb profile is not sharply defined. The outer part of the Sun varies continuously, so that over a height difference of about 400 km the solar gas density changes by a factor of 10—there is no unique definition of the Sun's limb. A 1 arcsecond change in the solar diameter corresponds to a solar radius change of 370 km.

Measurements of solar acoustic wave modes allow the possibility of detecting very small changes in solar radius. We can expect to observe changes in helioseismic mode frequencies caused by a changing solar diameter, just as the pitch of an organ pipe shifts when the length of the pipe changes. So far, helioseismic acoustic measurements yield no evidence of solar diameter changes larger than about 10 km over 1 year interval (see HELIOSEISMIC OBSERVATIONS).

Mechanisms for solar shape and size changes

The fluid outer regions of the Sun respond to gravitational, centrifugal and gas and turbulent pressure forces, so that the shape of the Sun yields a direct measure of the balance of these forces at the visible photosphere. For example, the solar oblateness can be directly related to the non-spherical solar quadrupole gravitational potential and the Sun's internal and surface rotation rates. The observed oblateness is entirely consistent with a Sun which rotates at approximately the observed surface rate, and which does not have a rapidly spinning inner core. The solar hexadecapole shape probably results from the variation in rotation rate with solar latitude.

We expect the Sun's diameter to change very slowly over millions of years because of variations in the internal solar structure caused by the Sun's nuclear evolution. While these diameter changes are too small for us to measure there have been inconsistent observational hints that the solar radius could be changing, perhaps with the solar cycle. Such changes, should they be detected, would be quite interesting because even a small change in the solar radius requires an enormous energy. For example, the energy required to lift just the outer convection zone of the Sun by 1 arcsecond (or 730 km) is equivalent to the total luminous energy of the Sun summed over 100 years. A physical mechanism that could cause such changes in diameter over a few years would also have profound consequences for our understanding of the internal solar structure.

Solar Interior: Standard Models

Due to its proximity, there are many properties of the Sun which we can observe. Consequently, it plays a key role in our understanding of the physics of the internal structure of stars. Standard models of the Sun are theoretical representations of its present structure. These models include the best physical description of the fundamental processes which contribute to solar evolution and allow theoretical predictions of all the solar observables. Testing against observations brings about theoretical improvements which are regularly implemented in standard models and new ideas for laboratory experiments (e.g. nuclear reaction rates, opacity measurements) or solar investigation (e.g. detailed photospheric abundances, acoustic modes, gravity modes, neutrino fluxes).

From the age of Earth to stellar evolution

If gravity were the main actor in the structure of the stars, one could easily calculate how long it would take for the Sun's own gravity to cause a significant change in its radius. The corresponding time scale is the free-fall time, $t_{\rm ff}$, which is a function of the mass M of the star, its radius R and the gravitational constant G:

$$t_{\rm ff} \propto \left(\frac{R^3}{GM}\right)^{1/2}. \quad (1)$$

This time is of the order of half an hour for the Sun, and is incompatible with its present extreme stability (see SUN: BASIC PROPERTIES). Another way of determining the age of the Sun is to correlate the rate of stellar evolution with the available energy. The gravitational potential energy has the following dimensional form: $\Omega \propto -M^2G/R$. For the Sun, $\Omega = 4 \times 10^{48}$ erg and the present luminosity is 4×10^{33} erg s^{-1}. The time scale over which the Sun could maintain more or less the present luminosity is called the Kelvin–Helmholtz time:

$$t_{\rm K} \propto \frac{\Omega}{L} \approx 30 \text{ Myr}. \quad (2)$$

This would give an order of magnitude for the solar age if one assumed a constant luminosity and no other energy losses. Until early in this century, people believed that the solar energy came from gravitational contraction, and that the Sun, and presumably the Earth, were a few million years old. However, the time scale required for biological evolution is considerably greater than $t_{\rm K}$, and this fact was at the origin of public disagreements between Darwin and Lord Kelvin. At about the same time, the geologist Sir Charles Lyell established that the ocean floor should be at least a billion years old in order to be compatible with features of sediments.

Later, Rutherford developed the radioactive dating of rocks, and it became evident that the Earth had to be several billion years old. However, the Sun should be at least as old as the Earth!

The thermonuclear source of energy stabilizes the Sun

Considering this contradiction, Eddington finally suggested in 1920 that perhaps a subatomic source of energy existed in stars and he introduced another concept, the Einstein time, which corresponds to the transformation into radiation of the total mass:

$$t_E = \frac{Mc^2}{L} = 14 \times 10^{12} \text{ yr}. \quad (3)$$

It then became evident that thermonuclear fusion had to play the fundamental role.

In fact, anticipating the result that the duration of hydrogen burning is about 10 billion years and that fusion occurs only in the inner part of the Sun (30–40% in mass fraction), one can deduce from the Einstein time that the efficiency of the conversion of mass to energy in the Sun is of the order of some per cent.

The present quiet Sun and most of the stars cannot be understood without their having an internal energy source that compensates for the energy lost at the surface. During stellar formation, nevertheless, gravity really is the main actor and its effect leads to an increase in the central temperature until nuclear fusion can deliver the energy required for a stationary equilibrium. After the first stage of deuterium burning, the Sun is limited in its contraction by the beginning of hydrogen burning; the beginning of this new phase is often called 'arrival on the main sequence' in stellar evolution.

Hydrogen, the most abundant element in stars, is also the first one to be converted because of its lower Coulomb barrier. Gamow, von Weizsacker and Bethe have shown clearly that two different sets of reactions, the p–p chain and the CNO cycles, could provide the energy needed to understand the present solar luminosity (see SOLAR INTERIOR: ENERGY GENERATION). The reactions involved in the conversion of hydrogen to helium depend on the temperature and density of the stellar interior. In fact, for the present solar central temperature, the p–p chain is the most energetic (more than 98% of the total luminosity), but when temperature increases, the CNO cycles quickly become the most efficient. One of the main consequences is that low-mass stars ($<1.5M\odot$), governed by p–p reactions, have a slower evolution than the others, governed by CNO cycles.

The stellar structure: the basic equations

Today, the origin of the Sun's stability is clearly established and it seems reasonable to treat the evolution of a star as a succession of static equilibrium models. Of course, the rapid contraction of the protostar which ignites the nuclear reactions must be examined with more caution. The main hypotheses are the following: the star is spherical, without the effect of rotation or a magnetic field. The internal structure of the star is described by four structure equations. The first assumes hydrostatic equilibrium (each gas shell is balanced by the competition between the

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

downward gravitational force and the outward pressure force):

$$\frac{\mathrm{d}P}{\mathrm{d}r} = -\frac{M(r)G}{r^2}\rho \tag{4}$$

where P and ρ are the pressure and the density. $M(r)$ represents the mass enclosed within a sphere of radius r:

$$\frac{\mathrm{d}M}{\mathrm{d}r} = 4\pi r^2 \rho. \tag{5}$$

One further assumes thermal equilibrium. The energy ($4\pi r^2 \rho\epsilon$) produced by nuclear reactions balances the energy flux $L(r)$ emerging from the sphere of radius r. To this energy flux must be added the energy loss by neutrinos (which is small in hydrogen burning but not in a supernova explosion). Taking into account quasistatic gravitational readjustment and composition variation, one must incorporate a heat transfer term $T\mathrm{d}S$ where S is the total entropy per gram of the gas and the energy bookkeeping yields:

$$\frac{\mathrm{d}L}{\mathrm{d}r} = 4\pi r^2 \rho \left(\epsilon_{\mathrm{nucl}} - \frac{T\mathrm{d}S}{\mathrm{d}t}\right). \tag{6}$$

At the end of hydrogen burning, the nuclear energy vanishes and again contraction produces the energy for the luminosity.

Finally, the temperature gradient depends on the luminosity and the physical process of energy transport. In a radiative region of a star, the diffusion approximation is appropriate, and the relation between temperature gradient and luminosity is

$$\frac{\mathrm{d}T}{\mathrm{d}r} = \frac{-3}{4ac}\frac{\kappa\rho}{T^3}\frac{L(r)}{4\pi r^2}. \tag{7a}$$

When the opacity coefficient κ increases too much, as in the external part of smaller stars with $M \leq 1.5M_\odot$ or when the luminosity is very high (in the internal part of stars with mass $>1.5M_\odot$), the radiative gradient increases so much that matter becomes convectively unstable. The resulting temperature gradient is then nearly adiabatic:

$$\frac{\mathrm{d}T}{\mathrm{d}r} = \left(\frac{\mathrm{d}T}{\mathrm{d}r}\right)_{\mathrm{ad}} = \frac{\Gamma_2 - 1}{\Gamma_2}\frac{T}{P}\frac{\mathrm{d}P}{\mathrm{d}r}. \tag{7b}$$

The adiabatic exponent Γ_2 is defined by

$$P^{1-\Gamma_2} T^{\Gamma_2} = \text{const.}$$

Boundary conditions (typically for pressure and temperature at the surface and for mass and luminosity at the center of the star) are added to complete the problem of stellar structure and evolution.

The physical quantities

The initial composition

The first ingredient of the calculation is the initial detailed composition of the Sun deduced from the observation of the present photospheric abundances. The determination of this composition is described in the article SOLAR ABUNDANCES. As it is now clear that there is some gravitational settling of elements during the lifetime of the Sun from the surface down to the center (see below), this composition is chosen to get the detailed photospheric composition at the present solar age and the whole calculation is iterated to get the observed present Z/X ratio at the surface (mass fraction of the elements greater than helium over hydrogen). Helium is not measured in the photosphere but helioseismology gives serious constraints on this abundance.

Recent calculations consider the 21 most important elements from hydrogen up to nickel. All elements up to ^{16}O contribute to calculation of the nuclear energy of the present Sun. The 21 elements are useful for precise opacity calculations.

The nuclear reaction rates

The nuclear reaction network is presented in the article on SOLAR INTERIOR: ENERGY GENERATION. That article includes the complete proton–proton chain and CNO cycles.

One can consider three types of species:

- Those which are only slowly produced or destroyed during stellar evolution (e.g. H, ^{4}He, ^{12}C). The evolution of the abundances is computed using a linearization method, semi-implicit or implicit.
- The very rapidly reacting minor species are assumed to be in local equilibrium and calculated separately (D, ^{7}Li, ^{7}Be).
- ^{3}He, an intermediate case, is treated analytically, assuming that deuterium has reached equilibrium and that the hydrogen abundance remains constant during a small nuclear time step. The assumption of ^{3}He in equilibrium is completely justified in the core of the Sun and becomes a rough approximation at $0.20R_\odot$. The treatment of ^{3}He is crucial for energy generation because the production of this element and its destruction by the reaction ^{3}He+^{3}He contributes to 80% of the total luminosity.

All nuclear reactions involving nuclei have been measured in the laboratory, except the p–p and pep reactions which are inaccessible due to the weak interaction. The most important cross sections have been generally measured in a higher energy range than needed for the Sun, therefore a theoretical extrapolation is often necessary. This effort is pursued nowadays at low energy in the laboratory to approach solar plasma conditions (see Adelberger *et al* 1998). Specific attention is paid to the Coulomb enhancement effect of the interaction, mainly due the presence of the negative cloud of the free electrons.

The equation of state

The relationship between pressure, temperature, density and composition called the *equation of state* must be known for very different conditions of matter (plasma, neutral atoms, molecules). The total pressure P is the sum of the gas pressure and radiation pressure.

The radiation pressure $P_R = \frac{1}{3}aT^4$, where a is the radiation density constant. is negligible in the solar center (1/1000 of the gas pressure), but not near the photosphere ($0.6P_G$). When the temperature is high and the density low enough, interactions between the particles are negligible and the gas can be reasonably well considered as perfect:

$$P_G = \frac{N}{V}kT = \frac{\rho kT}{\mu(r)} \tag{8}$$

where V is the volume of the gas. This approximation is relatively correct in the central part of the Sun for ions (see below for the treatment for electrons). But the large range of solar temperature (5×10^3 to 10^7 K) and density (10^{-12} to 10^2 g cm^{-3}) requires a more detailed description of the equation of state. As the Sun is made up of a mixture of different species, one introduces the notion of mean molecular weight μ, defined by

$$\mu^{-1} = \sum_i n_i(m_H/m_i). \tag{9}$$

In this expression, n_i is the number of free particles: Z electrons + 1 nucleus for each atom of atomic number Z. More generally, this number depends on the degree of ionization of the considered species. In astrophysics, X, Y and Z represent the mass fraction number (normalized to 1) of hydrogen, helium and other elements (heavier than helium) respectively. In the central conditions of the Sun, all the species (except iron and nickel) are completely ionized. The solar value μ decreases from the central region where helium is produced down to the nuclear edge. In the intermediate region of the Sun, the heavy elements become progressively partially ionized but this has little impact on μ which increases outward due to the partially ionized elements and the appearance of molecules.

Even though the correct treatment of the heavy elements affects the total pressure very little due to their small fraction number, this knowledge is important for opacity calculations (see below). The appropriate treatment of the degree of ionization of hydrogen and helium, together with a correct treatment of atomic and molecular hydrogen, is crucial to determine the pressure below 20 000 K.

The central solar density is sufficiently high to cause partial degeneracy of the electrons, so electron number and electron pressure must be expressed as functions of the degeneracy parameter η:

$$n_e = \frac{4\pi}{h^3}(2mkT)^{3/2}F_{1/2}(-\eta) \tag{10}$$

$$P_e = \frac{8\pi kT}{3h^3}(2mkT)^{3/2}F_{3/2}(-\eta)$$

where $F_{1/2}$ and $F_{3/2}$ are the Fermi–Dirac functions. In the case of the Sun, the effect of degeneracy is small (η is of the order of -1) but when stars continue to evolve, this effect becomes dominant, leading to an increase in the pressure and a quasi independence of the pressure on the temperature.

Relativistic and Coulomb effects must be taken into account to correct the gas pressure for electrostatic attraction. With the development of helioseismology, a sophisticated equation of state including all these processes and a large number of species may be checked in great detail, transforming the Sun into a real laboratory (cf SOLAR INTERIOR: EQUATION OF STATE AND OPACITY).

Energy transport

Two processes dominate the transport of energy in a solar-type star: radiation and convection. Conductivity plays no role in the Sun and acts only in higher-density stars (for example in a supernova core). In the same way, the energy transported by neutrinos is very small. In the central part of the Sun, radiation is the most efficient process, contrary to the case in more massive stars where energy is transported by convection due to the extremely high temperature produced by the CNO cycle.

Radiative transport

In the Sun's interior, the average energy per photon is in the keV range, which is characteristic of x-rays, whereas the light escaping from the surface is in the visible spectrum, corresponding to an energy 10^5 times smaller. The cause of this degradation in photon energy is the coupling between radiation and matter. The effect of the interaction of photons with electrons, atoms, ions and molecules is evaluated and is summarized in what one calls the 'Rosseland mean opacity' κ, which is a function of temperature, density and composition. The equation of radiative transfer adapted to stellar interiors is given by equation (7*a*). The opacity of the gas really governs the rate at which energy escapes, and plays a crucial role in determining the age of a star and the evolved central temperature. The sources of opacity are the following:

- electron scattering (Thompson and Compton scattering): scattering of the photon on free electrons;
- bound–bound transitions: the photon induces a modification of level at a bound electron;
- bound–free (photoionization) transitions: a bound electron becomes free after interaction with the photon or the reverse situation;
- free–free transitions (inverse bremsstrahlung): the electron stays free after the interaction with the photon;
- molecular transitions.

Except for the first one, the computation of all these processes necessitates detailed calculations of atomic physics. Frequency-dependent opacities are needed for detailed stellar models: $\kappa_{tot}(\nu) = \sum_i \kappa_i(\nu)$, where i

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

represents the different processes. It is important to notice that the mean Rosseland opacity is not obtained by averaging the frequency-dependent opacity, but by averaging its reciprocal, that is the radiative conductivity (the weight function $f(\nu)$ is the temperature derivative of the Planck function):

$$\frac{1}{\bar{\kappa}} = \sum_i \left(\int \frac{f(\nu)}{\kappa_i(\nu)} \mathrm{d}\nu \right). \tag{11}$$

The mean Rosseland value clearly favours peaks around $4\text{–}6h\nu/kT$ where the Rosseland weighting is maximum. This adds to the already nonlinear character of the processes and gives a supplementary reason to perform computations with an extremely refined grid well adapted to the problem. Moreover, due to the non-additive character of the opacity coefficients, the spectrum must be calculated for the correct mixture before determining the Rosseland mean value. This leads to extensive calculations which must take into account the detailed abundance of the 21 elements considered.

The main reason for the difficulty of such calculations is that one single source of opacity may exceed all the others. For example the bound–bound processes may introduce cross sections which are one or two orders of magnitude greater than the competing contributions.

So, even a trace element may produce a non-negligible contribution to the mean opacity. In the case of the Sun or solar-like stars, knowledge of radiative processes in detail is crucial. Indeed, in low-mass stars, the contribution of heavy elements (about 2% in mass fraction and 0.14% in number fraction) to the equation of state does not exceed 1 or 2%, but their contribution to the opacity is about 40% in the central part of the Sun, and 80% in the intermediate region. When oxygen (the most abundant heavy element) becomes partially recombined, the temperature gradient largely increases. Then nitrogen and carbon have the same behavior and the increase of κ is so important that the radiative temperature gradient exceeds the adiabatic one:

$$\left| \frac{\mathrm{d}T}{\mathrm{d}r} \right|_{\mathrm{rad}} > \left| \frac{\mathrm{d}T}{\mathrm{d}r} \right|_{\mathrm{ad}}. \tag{12}$$

This is the criterion for the onset of convective instability, called the Schwarzschild criterion. In the Sun, there is a large convective solar region below the photosphere which corresponds to such conditions, that oxygen then nitrogen, carbon and finally helium and hydrogen have important bound–bound contributions (figure 1). But at about $0.995R_\odot$, hydrogen and helium become neutral, the opacity decreases, radiative flux comes in competition with convective flux and a superadiabatic regime must be considered.

Convective transport

In any case, the energy must escape from the star. When the opacity increases too much, one would require a very steep temperature gradient to maintain the energy flow,

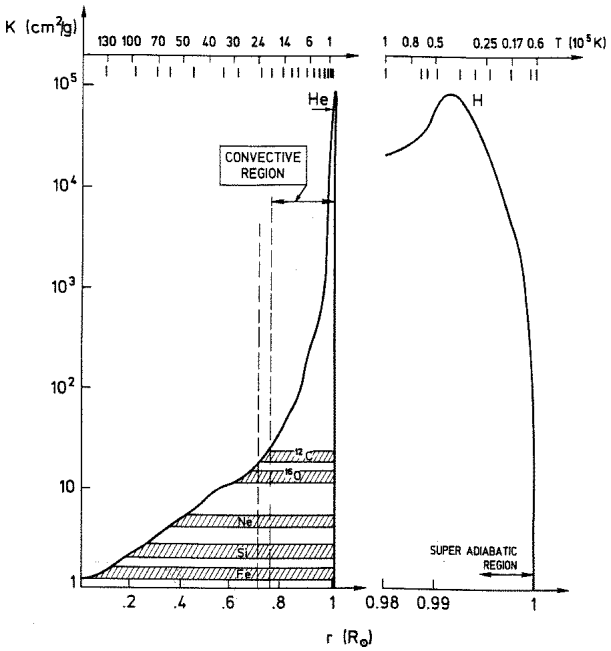

Figure 1. Present solar radial dependence of the total opacity κ ($\mathrm{cm}^2\ \mathrm{g}^{-1}$). The Sun has a large radiation region from the center down to $0.71R_\odot$. κ increases from the center to the photosphere with bound–bound processes. In this figure we show the radial position where the elements begin to be partly ionized. One notices that the base of the convective zone (broken lines) appears when oxygen (the third most abundant element) begins to have bound–bound contributors. A zoom of the external layers shows the role of partial ionization of helium then hydrogen; finally the formation of molecules induces a reduction of the opacity coefficients and new competition between convection and radiation in the superadiabatic region. The outermost layers are totally radiative.

leading to an unstable situation. When the instability criterion is fulfilled, the real temperature gradient exceeds the adiabatic gradient and the difference is called the superadiabatic gradient:

$$\frac{\Delta \mathrm{d}T}{\mathrm{d}r} \equiv \frac{\mathrm{d}T}{\mathrm{d}r} - \left(\frac{\mathrm{d}T}{\mathrm{d}r} \right)_{\mathrm{ad}} \tag{13}$$

Convection is a very efficient means of energy transport. In fact, near the base of the convective envelope, the radiative flux is so small that we can ignore the superadiabatic gradient and use the adiabatic one as the temperature gradient (this is also the case in the central part of massive stars). Unfortunately, this is not the case in the outer layers of the Sun. Evaluating this difference would require a theory of convection which is yet lacking; the simulation of such effects for stellar conditions is extremely complex (see SOLAR INTERIOR: CONVECTION THEORY), the size of the cells and the associated turbulence is not well established; so one usually restricts the calculation to an order of magnitude calculation in the framework of the 'mixing length theory'. This approximation conceptually

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

replaces the real situation of 'plumes', convective eddies of different sizes, by an average situation where each convective element travels, on average, a distance Λ, before mixing with the surrounding matter. This distance is generally scaled to the pressure scale height[1] by a parameter α called *the mixing length parameter*:

$$\Lambda = \alpha\lambda \equiv \alpha \left(\frac{\mathrm{d} \ln P}{\mathrm{d}r} \right)^{-1} . \qquad (14)$$

In this calculation, one must estimate the relative amount of energy carried by convection and by radiation. Two different cases must be studied: the convection in the central part of the star and in the outer layers. These two regions differ by their density values, respectively about 100 g cm^{-3} and 10^{-6} g cm^{-3}, and the typical lengths of Λ, 700 000 km and 200 km, so the difference between the temperature of a convective element and the average temperature of the surrounding matter is really very different in the two situations. In the central part of stars, the temperature gradient is about 10^{-4} K cm^{-1} to be compared with the absolute value of 10^7 K and a convective time of about 1 to 100 days. Therefore if such an instability exists (for stars greater than $1.5 M_\odot$), convection is an extremely efficient process of energy transport and the temperature gradient can safely be approximated by the adiabatic one. In the outer layers, the temperature variation between shells is of the order of 100 to 1000 K, to be compared with the gas temperature of 5000 to 10 000 K, the convective time is shorter, 1 to 100 min, and we really need an adapted treatment of the convection. In that case, due to partial ionization of hydrogen or helium, Γ_2 drops to a value near unity and the adiabatic gradient becomes relatively small. This favors convective transfer but the radiative flux is still important and cannot be neglected.

In the solar case, the value of the mixing length parameter is in fact calibrated in solar models by the knowledge of the solar radius at the Sun's present age. In this specific case, therefore, one may consider that this small superadiabatic region just below the photosphere is rather correctly treated. The extension of this solar value to other stars with rather different surface temperatures is more uncertain due to the fact that it is, amongst other things, largely dependent on the opacity in the superadiabatic part of the convection zone. This is why theoretical efforts to model convection, largely encouraged by the development of solar local helioseismology measurements are extremely promising.

The evolution of the Sun with time

The Sun is approximately in the middle of the first, longest (about 10 Gyr) and calm stage of stellar evolution, corresponding to the burning of hydrogen. A theoretical description of the evolution of the Sun with time is obtained by considering a succession of static equilibrium models described by the basic equations (4) to (7). The time evolution of each chemical species X_i is given by three terms:

$$\frac{\mathrm{d}X_i}{\mathrm{d}t} = \frac{\mathrm{d}X_i}{\mathrm{d}t}_{\text{ nucl}} + \frac{\mathrm{d}X_i}{\mathrm{d}t}_{\text{ diff}} + \frac{\mathrm{d}X_i}{\mathrm{d}t}_{\text{ turb}} . \qquad (15)$$

The first term is the major one for the evolution of a star. It determines the evolved composition due to the differing destruction and creation of elements through nuclear reactions. It allows also us to determine the nuclear energy ϵ_{nucl} of equation (6). Starting from an initial mass fraction of 0.71, the present relative abundance of hydrogen in the central region is 0.34 and the helium has increased in consequence (from 0.27 to 0.63). The main important elements and their radial distributions are shown in figure 2. One notices very different compositions and largely different radial distributions due to nuclear processes. The second term has recently been introduced into the equations to take into account microscopic diffusion. This very slow process of elemental diffusion with a characteristic time-scale of 10^{10} years, is theoretically studied as a partial solution to the observed deficit of some 'fragile' element such as lithium, which is destroyed at about 2.4×10^6 K in typical solar mass conditions.

The introduction of such a process has been largely validated by the capability of helioseismology to determine the photospheric solar helium. The value of 0.249 ± 0.003 in *mass fraction* is very near the cosmological value (0.23–0.24) but rather incompatible with the assumption that the initial solar composition is the present photospheric one. Effectively the initial helium abundance of 0.27, obtained by the standard solar model, shows a reasonable galaxy enrichment between the Big Bang and the formation of the solar system. Consequently this second term is definitively introduced in the equations describing the standard solar model.

The diffusive velocity V_i of an element i, typically some 10^{-8} cm s^{-1}, is the result of several processes with opposing directions, including gravitational settling, radiative and thermal terms. The net result is a slight migration of all elements heavier than hydrogen towards the center with time. At the present time, the photospheric abundances are depleted by about 10% in comparison with their initial value due to these processes.

The last term in equation (15) represents a turbulent term which simulates macroscopic motion inside the Sun. This term is generally ignored in the standard model but begins to be considered at the basis of the convective zone. In this region of transition between radiation and convection, macroscopic motions and mixing could be induced by the differential rotation, which is now observed rather precisely by seismology. Such a process partly inhibits the microscopic diffusion.

Confrontation of standard models with observations

The stellar evolution codes were developed in the 1960s and early 1970s when computers were expanding in power, memory and speed. The codes solve the basic

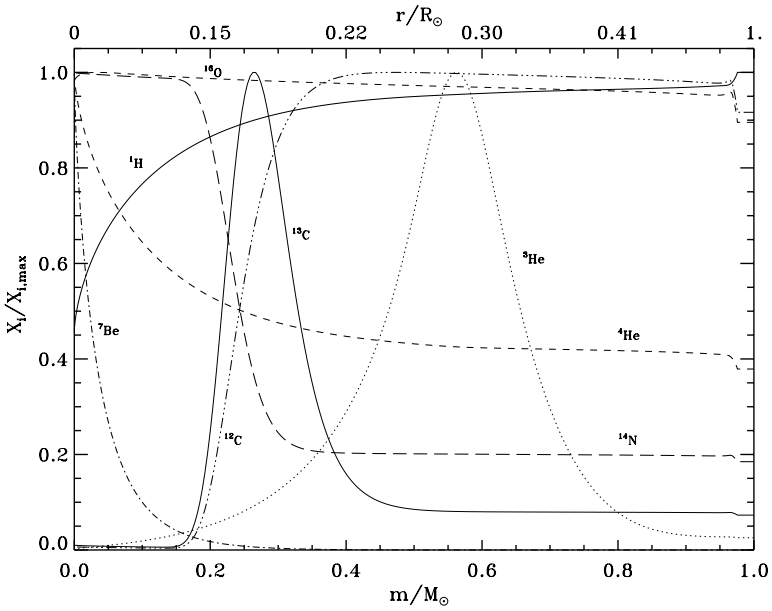

Figure 2. Radial dependence of the abundances of the most crucial elements which have been modified by nuclear reactions. The maximum values are the following: H = 0.7204, ^{3}He = 0.003 09, ^{4}He = 0.6350, ^{7}Be = 1.718×10^{-11}, ^{12}C = 0.0030, ^{13}C = 0.000 44, ^{14}N = 0.0045, ^{16}O = 0.0085.

equations (4) to (7) generally expressed in Lagrangian coordinates following the motion of mass elements. The starting point is usually an isolated non-rotating, non-magnetic spherical mass of gas. In that early period, methods and codes were developed by Iben, Paczyński and Kippenhahn. The most recent ones have introduced numerical methods which guarantee a high accuracy (typically 10^{-7}), useful to avoid any numerical effect in the interpretation of the present solar observables.

At each time step, the spatial stellar structure is described with the help of 300 to 600 mesh points the nonlinear differential equations are solved with the five structural variables, pressure $P = P(\rho, T, X_i)$, opacity coefficient $\kappa = \kappa(\rho, T, X_i)$, energy production $\epsilon = \epsilon(\rho, T, X_i)$, entropy $S = S(\rho, T, X_i)$ and adiabatic exponent $\Gamma_2 = \Gamma_2(\rho, T, X_i)$. The initial model is built in such a way that it simulates the stellar equilibrium corresponding to the moment when the contraction of the star is stopped by the onset of hydrogen burning; it may also be built to include the gravitational contraction of the pre-main sequence (see PRE-MAIN SEQUENCE STARS). One then follows stellar time evolution through a succession of hydrostatic equilibria. The time step is automatically adjusted and determined by the maximum acceptable variation of the principal variables.

The simulation of the present Sun is based on the previous concepts. The peculiarity of the Sun as a star is due to direct comparison with a variety of observed phenomena. The known present luminosity $L_\odot$ and radius $R_\odot$, as well as the age, avoid the two main difficulties of the theory of stellar evolution: the absence of a precise determination of helium abundance and of an *ab initio* theoretical formalism for convection.

Table 1 summarizes the results obtained by standard model calculations, compared with present observations. Starting with a star of $1M_\odot$, just on the arrival of the main sequence or in the pre-main sequence contracting phase, with an initial composition provided by present observation, we solve the structure equations (4) to (7) and (15) and progress in time by successive steps of the equilibrium state, including nuclear and diffusion processes, up to the present time estimated to be 4.52–4.55 Gyr. The computation is done *ab initio*, without any free parameters. The computation of the reference model is iterated with small modifications of the initial helium content Y, the initial heavy element composition, and the parameter α in order to obtain the observed values $L_\odot$, $R_\odot$ and $Z/X_\odot$ at $t_\odot$. The solar structure is more and more under control, from a standard model without diffusion to a standard model including microscopic diffusion and some turbulent mixing at the base of the convective zone, with very good agreement for the photospheric helium and the position of the base of the convective zone between the latest model and the results obtained by inversion of the sound speed and the adiabatic exponent Γ_1 ($c^2 = \Gamma_1 P/\rho$) (see HELIOSEISMOLOGY: THEORY).

Figures 3(*a*) and (*b*) present the corresponding squared sound speed difference between the Sun and these models. The present errors on the solar sound speed vary from about a few parts in 10^5 near the surface to a few parts in 10^4 in the solar core. Such an accuracy allows us to check some reaction rates ((p,p) or ^{3}He,^{4}He) or opacity questions at the level of some 1% or equation of state ones

Table 1. Standard solar models. Thermodynamical quantities and neutrino predictions obtained in the computation of the standard model: the present $R_\odot$ and $L_\odot$ are adjusted to $(6.9599 \pm 0.0002) \times 10^{10}$ cm and $(3.846 \pm 0.004) \times 10^{33}$ ergs s^{-1} respectively, α is the mixing length parameter; Y_i, Z_i, $(Z/X)_i$ are initial helium, initial heavy element and initial ratio heavy element to hydrogen; Y_s, Z_S, $(Z/X)_S$ are the same for photospheric compositions; R_{bcz}, T_{bcz} are the radius and temperature at the base of the convective zone; Y_c, Z_c, T_c, ρ_c are central helium, heavy element contents, central temperature and density; ^{37}Cl, ^{71}Ga, ^{8}B respective neutrino predictions for the chlorine, gallium and water detectors.

Parameters	Observations	Without diffusion	With diffusion	With diff. + turb
α		1.71	1.77	1.76
Y_i		0.265	0.272	0.272
Z_i		1.757×10^{-2}	1.898×10^{-2}	1.898×10^{-2}
$(Z/X)_i$		0.0245	0.0277	0.0277
Y_s	0.249 ± 0.003	0.265	0.243	0.251
Z_s		1.757×10^{-2}	1.803×10^{-2}	1.858×10^{-2}
$(Z/X)_s$	$0.0245 \times (1 \pm 0.1)$	0.0245	0.0245	0.0255
$R_{bcz}/R_\odot$	0.713 ± 0.003	0.729	0.713	0.714
$T_{bcz} \times 10^6$ (K)		2.055	2.190	2.194
Y_c		0.614	0.640	0.641
Z_c		1.807×10^{-2}	2.094×10^{-2}	2.094×10^{-2}
$T_c \times 10^6$ (K)		15.44	15.71	15.71
ρ_c (g cm^{-3})		147.80	153.1	153.1
^{37}Cl (SNU)	2.55 ± 0.25 SNU	5.65	7.04 ± 1.8	7.04 ± 1.8
^{71}Ga (SNU)	76 ± 8 SNU (cal $= 0.91 \pm 0.08$)	119.4	127.1 ± 9	127.1 ± 9
^{8}B (10^6 cm^{-2} s^{-1})	2.44 ± 0.26	3.66	$5. \pm 1.25$	$5. \pm 1.25$

at the level of some 0.1%. So, comparisons with precise helioseismological data push astrophysicists to use the best physical developments available in atomic, nuclear and plasma physics, and the results are representative of this knowledge.

Nevertheless, figures 3(*a*) and (*b*) show regions of mismatch where the differences on the squared sound speed between model and Sun is about 10 times the experimental determination of such a quantity. These regions are useful to correct the physics used or to introduce a new phenomenon, as has been done for the two processes explicitly discussed here. The residual difference may be attributed to uncertainties on abundances, opacities or reaction rates.

The results are reproducible, except to some extent in the solar nuclear core where solar results are sensitive to the data used and the model results depend on the details of most of the physical inputs. The core of the Sun is not totally under control, and this justifies complementary efforts to try to detect gravity waves which will help us to better investigate this region of the Sun and to disentangle different physical effects.

The neutrino fluxes obtained by the standard models are not in agreement with the observations. Helioseismology constrains the situation offered by the stellar structural problem even if it does not at present sufficiently constrain the region of interest located below $0.15R_\odot$. Nuclear reaction rates in the secondary channels (as the ppIII chain) or absorption cross sections play a crucial role in these predictions. Experimental and theoretical efforts in these disciplines continue to be useful as they are potentially able to explain some of the discrepancy. In parallel the study of the properties of neutrinos is also required to get a definitive understanding of solar neutrino fluxes on the ground (see SOLAR INTERIOR: NEUTRINOS).

Toward a dynamical representation of the stars

The present theoretical description of the Sun is a static monodimensional representation of our star where rotation and magnetic field are not yet introduced explicitly. The development of local seismology and three-dimensional simulation of convection contribute to progress towards a dynamical representation of the Sun. Nowadays the differential rotation coupled with turbulent convection improve the agreement with observations and encourages three-dimensional representation of the Sun in order to disentangle the internal competitive physical processes.

Some complementary indicators are specific abundances such as photospheric ^{3}He, ^{7}Li and ^{9}Be abundances, which have a certain sensitivity to internal mixing as they are destroyed outside the nuclear core (see figure 2). One may notice that the destruction of lithium occurs partly during the pre-main sequence and the main sequence. The understanding of the observed deficit of present photospheric lithium is largely dependent on the competition of photon-matter absorption, element segregation and turbulent diffusion.

The development of asterosismology (seismic study of solar-like stars) may contribute to refining our representation of the Sun by properly introducing the dynamical processes of the young Sun.

The internal magnetic field is still rather poorly known; a global history of the angular momentum of the

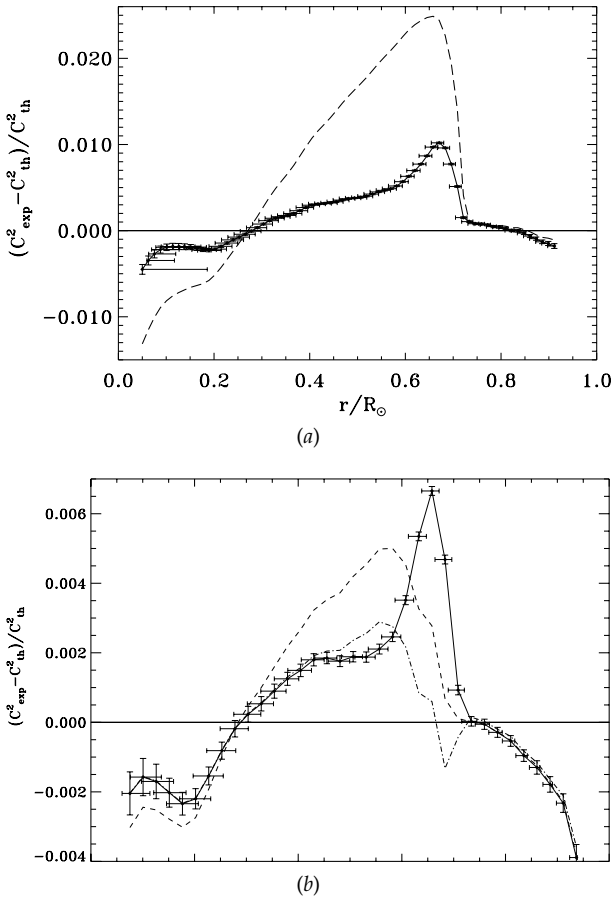

Figure 3. Sound speed squared difference between the Sun measured by GOLF+LOWL experiments and standard models. The seismic uncertainties are reported on the difference itself. No theoretical uncertainty is included. (*a*) corresponds to standard models without (full) (model 1, table 1) and with microscopic diffusion (full line with experimental error bars, model 2, table 1). (*b*) corresponds to the model including microscopic diffusion (model 2, table 1) and to the model where a turbulent term is added at the base of the convective zone (model 3, table 1).

Sun coupled to temporal seismic studies along the solar cycle could help progress in this direction.

The very specific study of the solar interior is crucial for the understanding of general astrophysics problems such as the age of the universe, galactic evolution, the role of convection etc. It also plays a crucial role in understanding the properties of neutrinos.

Solar Irradiance

Irradiance is the power from a source of radiant energy that is incident on unit area of a surface located at some distance from the source. The Sun's total irradiance is 1365 ± 2 W m^{-2}. This is the total radiant energy per unit time (i.e. power) at all wavelengths that the Earth receives on unit area of its surface from the entire solar disk when separated from the Sun by one astronomical unit (1 AU $= 1.49 \times 10^{13}$ cm).
